Abstract. Ratios of normalizing constants for two distributions are needed in both Bayesian statistics, where they are used to compare models, and in statistical physics, where they correspond to differences in free energy. Two approaches have long been used to estimate ratios of normalizing constants. The 'simple importance sampling' (SIS) or 'free energy perturbation' method uses a sample drawn from just one of the two distributions. The 'bridge sampling' or 'acceptance ratio' estimate can be viewed as the ratio of two SIS estimates involving a bridge distribution. For both methods, difficult problems must be handled by introducing a sequence of intermediate distributions linking the two distributions of interest, with the final ratio of normalizing constants being estimated by the product of estimates of ratios for adjacent distributions in this sequence. Recently, work by Jarzynski, and independently by Neal, has shown how one can view such a product of estimates, each based on simple importance sampling using a single point, as an SIS estimate on an extended state space. This 'Annealed Importance Sampling' (AIS) method produces an exactly unbiased estimate for the ratio of normalizing constants even when the Markov transitions used do not reach equilibrium. In this paper, I show how a corresponding 'Linked Importance Sampling' (LIS) method can be constructed in which the estimates for individual ratios are similar to bridge sampling estimates. As a further elaboration, bridge sampling rather than simple importance sampling can be employed at the top level for both AIS and LIS, which sometimes produces further improvement. I show empirically that for some problems, LIS estimates are much more accurate than AIS estimates found using the same computation time, although for other problems the two methods have similar performance. Like AIS, LIS can also produce estimates for expectations, even when the distribution contains multiple isolated modes. AIS is related to the 'tempered transition' method for handling isolated modes, and to a method for 'dragging' fast variables. Linked sampling methods similar to LIS can be constructed that are analogous to tempered transitions and to this method for dragging fast variables, which may sometimes work better than those analogous to AIS.

1 Introduction

Consider two distributions on the same space, with probability mass or density functions $\pi_0(x) = p_0(x)/Z_0$ and $\pi_1(x) = p_1(x)/Z_1$. Suppose that we are not able to directly compute π_0 and π_1, but only p_0 and p_1, since we do not know the normalizing constants, Z_0 and Z_1. We wish to find a Monte Carlo estimate for the ratio of these normalizing constants, Z_1/Z_0, which we sometimes denote by r, using samples of values drawn (at least approximately) from π_0 and from π_1. Sometimes, we may know Z_0, in which case we can arrange for it to be one, so that estimation of this ratio will give the numerical value of Z_1. Other times, we will be able to obtain only the ratio of normalizing constants, but this may be sufficient for our purposes.

In statistical physics, x represents the state of some physical system, and the distributions are typically 'canonical' distributions having the following form (for $j = 0, 1$):

$$p_j(x) \quad = \quad \exp(-\beta_j U(x, \lambda_j)) \tag{1}$$

where $U(x, \lambda_j)$ is an 'energy' function, which may depend on the parameter λ_j, and β_j is the inverse temperature of system j. Many interesting properties of the systems are related to the 'free energy', defined as $-\log(Z_j) \,/\, \beta_j$. Often, only the difference in free energy between systems 0 and 1 is relevant, and this is determined by the ratio Z_1/Z_0.

In Bayesian statistics, x comprises the parameters and latent variables for some statistical model, π_0 is the prior distribution for these quantities (for which the normalizing constant is usually known), and π_1 is the posterior distribution given the observed data. We can compute $p_1(x)$ as the product of the prior density for x and the probability of the data given x, but the normalizing constant, Z_1, is difficult to compute. We can interpret Z_1 as the 'marginal likelihood' — the probability of the observed data under this model, integrating over possible values of the model's parameters and latent variables. The marginal likelihood for a model indicates how well it is supported by the data.

Although I will use simple distributions as illustrations in this paper, in real applications, x is usually high dimensional, and at least one of π_0 and π_1 is usually quite complex. Accordingly, sampling from these distributions generally requires use of Markov chain methods, such as the venerable Metropolis algorithm (Metropolis, *et al* 1953). See (Neal 1993) for a review of Markov chain sampling methods. Sometimes, however, π_0 will be relatively simple, and independent points drawn from it can be generated efficiently, as would often be the case with the prior distribution for a Bayesian model, or for a physical system at infinite temperature ($\beta_0 = 0$).

Many methods for estimating ratios of normalizing constants from Monte Carlo data have been investigated in the physics literature (for a review, see (Neal 1993, Section 6.2)), and later rediscovered in the statistics literature (Gelman and Meng 1998). A logical method to start with is 'simple importance sampling' (SIS), also called 'free energy perturbation', based on the following identity, which can easily be proved on the assumption that no region having zero probability under π_0 has

non-zero probability under π_1:

$$\frac{Z_1}{Z_0} \;=\; E_{\pi_0}\left[\frac{p_1(X)}{p_0(X)}\right] \;\approx\; \frac{1}{N}\sum_{i=1}^{N}\frac{p_1(x^{(i)})}{p_0(x^{(i)})} \;=\; \frac{1}{N}\sum_{i=1}^{N}\hat{r}_{\mathrm{SIS}}^{(i)} \;=\; \hat{r}_{\mathrm{SIS}} \tag{2}$$

In the above equation, E_{π_0} denotes an expectation with respect to the distribution π_0, which is estimated by a Monte Carlo average over points $x^{(i)}, \ldots, x^{(N)}$ drawn from π_0 (either independently, or using a Markov chain sampler). Here and later, $\hat{r}_{\mathrm{M}}$ will denote an estimate of $r = Z_1/Z_0$, found by method M. If this estimate is an average of unbiased estimates based on a number of samples, these individual estimates will be denoted by $\hat{r}_{\mathrm{M}}^{(i)}$.

The simple importance sampling estimate, $\hat{r}_{\mathrm{SIS}}$, will be poor if π_0 and π_1 are not close enough — in particular, if any region with non-negligible probability under π_1 has very small probability under π_0. Such a region would have an important effect on the value of r, but very little information about it would be contained in the sample from π_0. In such a situation, it may be possible to obtain a good estimate by introducing intermediate distributions. Parameterizing these distributions in some way using η, we can define a sequence of distributions, $\pi_{\eta_0}, \ldots, \pi_{\eta_n}$, with $\eta_0 = 0$ and $\eta_n = 1$ so that the first and last distributions in the sequence are π_0 and π_1, with the intermediate distributions interpolating between them. We can then write

$$\frac{Z_1}{Z_0} \;=\; \prod_{j=0}^{n-1}\frac{Z_{\eta_{j+1}}}{Z_{\eta_j}} \tag{3}$$

Provided that $\pi_{\eta_{j+1}}$ and π_{η_j} are close enough, we can estimate each of the factors $Z_{\eta_{j+1}}/Z_{\eta_j}$ using simple importance sampling, and from these estimates obtain an estimate for Z_1/Z_0.

We can obtain good estimates in a wider range of situations, or using fewer intermediate distributions (sometimes none), by applying a technique introduced by Bennett (1976), who called it the 'acceptance ratio' method. This method was later rediscovered by Meng and Wong (1996), who called it 'bridge sampling'. Lu, Singh, and Kofke (2003) provide a recent review and assessment. One way of viewing this method is that it replaces the simple importance sampling estimate for Z_1/Z_0 by a ratio of estimates for Z_*/Z_0 and Z_*/Z_1, where Z_* is the normalizing constant for a 'bridge distribution', $\pi_*(x) = p_*(x)/Z_*$, which is chosen so that it is overlapped by both π_0 and π_1. Using simple importance sampling estimates for Z_*/Z_0 and Z_*/Z_1, we can obtain the estimate

$$\frac{Z_1}{Z_0} \;=\; E_{\pi_0}\left[\frac{p_*(X)}{p_0(X)}\right] \Big/ E_{\pi_1}\left[\frac{p_*(X)}{p_1(X)}\right] \;\approx\; \frac{1}{N_0}\sum_{k=1}^{N_0}\frac{p_*(x_{0,k})}{p_0(x_{0,k})} \Big/ \frac{1}{N_1}\sum_{k=1}^{N_1}\frac{p_*(x_{1,k})}{p_1(x_{1,k})} \;=\; \hat{r}_{\mathrm{bridge}} \tag{4}$$

where $x_{0,1}, \ldots, x_{0,N_0}$ are drawn from π_0 and $x_{1,1}, \ldots, x_{1,N_1}$ are drawn from π_1.

One simple choice for the bridge distribution is the 'geometric' bridge:

$$p_*^{\mathrm{geo}}(x) \;=\; \sqrt{p_0(x)p_1(x)} \tag{5}$$

which is in a sense half-way between π_0 and π_1. As discussed by Bennett (1976) and by Meng and Wong (1996), the asymptotically optimal choice of bridge distribution is

$$p_*^{\mathrm{opt}}(x) \;=\; \frac{p_0(x)p_1(x)}{r(N_0/N_1)p_0(x) \,+\, p_1(x)} \tag{6}$$

where $r = Z_1/Z_0$. Of course, we cannot use this bridge distribution in practice, since we do not know r. We can use a preliminary guess at r to define an initial bridge distribution, however, which will give us a bridge sampling estimate for Z_1/Z_0. Using this estimate as the new value of r, we can refine our bridge distribution, iterating this process as many times as desired. The result of this iteration can also be viewed as a maximum likelihood estimate for r, as discussed by Shirts, *et al* (2003), who argues on this basis that it is asymptotically as good as any estimate for r. I have found that estimates with r set iteratively are often better than those found with the true value of r (which does not contradict optimality of the true value for a fixed choice of bridge distribution).

If π_0 and π_1 do not overlap sufficiently, no bridge distribution will produce good estimates, and we will have to introduce intermediate distributions as in equation (3). Note, however, that the bridge sampling estimate with either of the above bridge distributions converges to the correct ratio asymptotically as long there is some region that has non-zero probability under both π_0 and π_1, a much weaker requirement than that for simple importance sampling.

This advantage of bridge sampling over SIS can be seen in a simple example involving distributions that are uniform over an interval of the reals. Let $p_0(x) = I_{(0,3)}(x)$ and $p_1(x) = I_{(2,4)}(x)$, so that $Z_0 = 3$ and $Z_1 = 2$. The simple importance sampling estimate of equation (2) does not work, as it converges to 1/3 rather than 2/3. However, using a bridge distribution with $p_*(x) = I_{(2,3)}$, which is effectively what both p_*^{opt} and p_*^{geo} will be in this example, the bridge sampling estimate of equation (4) converges to the correct value, since the numerator converges to 1/3 and the denominator to 1/2.

Although both simple importance sampling and bridge sampling have been successfully used in many applications, they have some deficiencies. One issue is that although the SIS estimate of equation (2) is unbiased for Z_1/Z_0, the bridge sampling estimate of equation (4) is not, and the same would appear to be the case for an estimate using intermediate distributions (via equation (3)). This is of no direct importance, particularly since we are often more interested in $\log(Z_1/Z_0)$ than in Z_1/Z_0 itself. However, it does preclude averaging independent replications of the bridge sampling estimate to obtain a better estimate, since the bias would prevent convergence to the correct value as the number of replications increases. A more vexing difficulty is that, except sometimes for π_0, sampling from the distributions π_η must usually be done by Markov chain methods, which approach the desired distribution only asymptotically. To speed convergence, the Markov chain for sampling π_{η_j} is often started from the last state sampled for $\pi_{\eta_{j-1}}$, but it is unclear how many iterations should then be discarded before an adequate approximation to the correct distribution is reached.

Surprisingly, these difficulties can be completely overcome when using simple importance sampling with a single point. As shown by Jarzynski (1997, 2001), and later independently by myself (Neal 2001), an estimate for Z_1/Z_0 using intermediate distributions as in equation (3) will be exactly unbiased if

each of the ratios $Z_{\eta_{j+1}}/Z_{\eta_j}$ is estimated using the simple importance sampling estimate of equation (2) with $N = 1$, sampling each distribution with a Markov chain update starting with the point for the previous distribution. Averaging the estimates obtained from M independent replications of this process (called 'runs') produces the following estimate:

$$\frac{Z_1}{Z_0} \approx \frac{1}{M} \sum_{i=1}^{M} \prod_{j=0}^{n-1} \frac{p_{\eta_{j+1}}(x_j^{(i)})}{p_{\eta_j}(x_j^{(i)})} = \frac{1}{M} \sum_{i=1}^{M} \hat{r}_{\mathrm{AIS}}^{(i)} = \hat{r}_{\mathrm{AIS}} \tag{7}$$

Here, $x_0^{(1)}, \ldots, x_0^{(M)}$ are drawn independently from π_0, and each $x_j^{(i)}$ for $j > 0$ is generated by applying a Markov chain transition that leaves π_{η_j} invariant to $x_{j-1}^{(i)}$. This single Markov transition (which could, however, consist of several Metropolis or other updates if we so choose), will usually not be enough to reach equilibrium, but the estimate $\hat{r}_{\mathrm{AIS}}$ is nevertheless exactly unbiased, and will converge to the true value as M increases, provided that no region having zero probability under π_{η_j} has non-zero probability under $\pi_{\eta_{j+1}}$. This can be proved by showing how the estimate above can be seen as a simple importance sampling estimate on an extended state space that includes the values sampled for the intermediate distributions.

I call this method 'Annealed Importance Sampling' (AIS), since the sequence of distributions used often corresponds to an 'annealing' procedure, in which the temperature is gradually decreased. As I discuss in (Neal 2001), this allows the procedure to sample different isolated modes of the distribution on different runs, properly weighting the points obtained from each of these runs to produce the correct probability for each mode. AIS is related to an earlier method for moving between isolated modes that I call 'tempered transitions' (Neal 1996). In a recent paper (Neal 2004), I show how tempered transitions can be modified to produce a method for efficient Markov chain sampling when some of the state variables are 'fast' — ie, when it is possible to more quickly recompute the probability of a state when only these fast variables change than when the other 'slow' variables change as well. In this method, the fast variables are 'dragged' through intermediate distributions in order to produce more appropriate values to go with a proposed change to the slow variables. Deciding whether to accept the final proposal involves what is in effect an estimate of the ratio of normalizing constants for the conditional distributions of the fast variables.

In this paper, I show how the ideas behind Annealed Importance Sampling and bridge sampling can be combined. I call the resulting method 'Linked Importance Sampling' (LIS), since the two samples needed for bridge sampling are linked by a single state that is used in both. Intermediate distributions can be used, with each distribution being linked by a single state to the next distribution. In contrast to bridge sampling, LIS estimates are unbiased, and as is the case for AIS, they remain exactly unbiased even when intermediate distributions are used, and when sampling is done using Markov chain transitions that have not converged to their equilibrium distributions.

Crooks (2000) mentions a different way of combining AIS with bridge sampling — since AIS estimates are simple importance sampling estimates on an extended state space, we can combine 'forward' and 'reverse' estimates to produce a bridge sampling estimate that may be superior. I will call this

method 'bridged AIS'. Similarly, such a top-level application of bridge sampling can be combined with the low-level application of bridge sampling in LIS, giving what I call 'bridged LIS'.

Using tests on sequences of one-dimensional distributions, I demonstrate that for some problems LIS is much more efficient than AIS — a result that should be expected, since in extreme cases, such as for the uniform distributions discussed above, the simple importance sampling estimates underlying AIS do not converge to the correct answer even asymptotically, whereas bridge sampling estimates do. For some other problems, however, AIS and LIS perform about equally well. The bridged version of AIS sometimes performs much better than the unbridged version, but still performs less well than LIS and its bridged version on some problems. I also analyse the asymptotic properties of AIS and LIS for some types of distribution, providing additional insight into their behaviour.

Variants of tempered transitions and of my method for dragging fast variables can be constructed that are analogous to LIS rather than to AIS. I discuss the 'linked' variant of tempered transitions briefly, and include a more detailed description of a linked version of dragging, which may sometimes be better than the version related to AIS. I conclude by discussing some possibilities for future research.

2 The Linked Importance Sampling procedure

Assume that we can evaluate the unnormalized probability or density functions $p_\eta(x)$, for any value of the parameter η, with the normalized form of such a distribution being denoted by π_η. The values $\eta = 0$ and $\eta = 1$ define the two distributions we are interested in, for which the normalizing constants are Z_0 and Z_1. A sequence of $n-1$ intermediate values for η define distributions that will assist in estimating the ratio of these normalizing constants, $r = Z_1/Z_0$. We denote the values of η for the distributions used by $\eta_0, \ldots, \eta_n$, with $\eta_0 = 0$ and $\eta_n = 1$. Typically, $\eta_j < \eta_{j+1}$ for all j.

For problems in statistical physics, η might be proportional to the inverse temperature, β, of equation (1), or might map to a value for λ. For a Bayesian inference problem, η might be a power that the likelihood is raised to, so that $\eta = 0$ causes the data to be ignored, and $\eta = 1$ gives full weight to the data; the ratio Z_1/Z_0 will then be the marginal likelihood. In both of these examples, progressing in small steps from $\eta = 0$ to $\eta = 1$ is not only useful in estimating Z_1/Z_0, but also often has an 'annealing' effect, which helps avoid being trapped in a local mode of the distribution.

2.1 Details of the LIS procedure

For each distribution, π_η, assume we have a pair of Markov chain transition probability (or density) functions, denoted by $T_\eta(x, x')$ and $\underline{T}_\eta(x, x')$, satisfying $\int T_\eta(x, x')dx' = 1$ and $\int \underline{T}_\eta(x, x')dx' = 1$, for which the following mutual reversibility relationship holds:

$$\pi_\eta(x)\, T_\eta(x, x') \;\; = \;\; \pi_\eta(x')\, \underline{T}_\eta(x', x), \qquad \text{for all } x \text{ and } x' \tag{8}$$

From this relationship, one can easily show that both T_η and $\underline{T}_\eta$ leave π_η invariant — ie, that $\int \pi_\eta(x) T_\eta(x, x')dx = \pi_\eta(x')$, and the same for $\underline{T}_\eta$. If T_η is reversible (ie, satisfies 'detailed balance'),

then $\underline{T}_\eta$ will be the same as T_η. Non-reversible transitions often arise when components of state are updated in some predetermined order, in which case the reverse transition simply updates components in the opposite order. As a special case, T_η might draw the next state from π_η independently of the current state. Such independent sampling may often be possible for T_0.

These Markov chain transitions are used to obtain samples that are approximately drawn from each of the $n+1$ distributions, $\pi_{\eta_0}, \ldots, \pi_{\eta_n}$. We assume that we can begin sampling from π_0 by drawing a single point independently from π_0. For $j > 0$, we begin sampling from π_{η_j} by selecting a link state, x_{j-1*j}, from the sample associated with $\pi_{\eta_{j-1}}$. For all j, we produce a sample of K_j+1 states from this starting point by applying a total of K_j forward (T_{η_j}) or reversed ($\underline{T}_{\eta_j}$) Markov transitions. Link states are selected using bridge distributions, p_{j*j+1}, which are defined in terms of p_{η_j} and $p_{\eta_{j+1}}$, perhaps using the form of equation (5) or (6), with p_0 replaced by p_{η_j} and p_1 by $p_{\eta_{j+1}}$.

In detail, the Linked Importance Sampling procedure produces M estimates, $\hat{r}^{(1)}_{\rm LIS}, \ldots, \hat{r}^{(M)}_{\rm LIS}$, that are averaged to produce the final estimate, $\hat{r}_{\rm LIS}$. Each $\hat{r}^{(i)}_{\rm LIS}$ is obtained by performing the following:

The LIS Procedure

1) Pick an integer ν_0 uniformly at random from $\{0, \ldots, K_0\}$, and then set x_{0,ν_0} to a value drawn from π_{η_0}.

2) For $j = 0, \ldots, n$, sample K_j+1 states drawn (at least approximately) from π_{η_j} as follows:

   a) If $j > 0$: Pick an integer ν_j uniformly at random from $\{0, \ldots, K_j\}$, and then set x_{j,ν_j} to x_{j-1*j}.

   b) For $k = \nu_j + 1, \ldots, K_j$, draw $x_{j,k}$ according to the forward Markov chain transition probabilities $T_{\eta_j}(x_{j,k-1}, x_{j,k})$. (If $\nu_j = K_j$, do nothing in this step.)

   c) For $k = \nu_j - 1, \ldots, 0$, draw $x_{j,k}$ according to the reverse Markov chain transition probabilities $\underline{T}_{\eta_j}(x_{j,k+1}, x_{j,k})$. (If $\nu_j = 0$, do nothing in this step.)

   d) If $j < n$: Pick a value for μ_j from $\{0, \ldots, K_j\}$ according to the following probabilities:

$$\Pi_0(\mu_j \,|\, x_j) \;=\; \frac{p_{j*j+1}(x_{j,\mu_j})}{p_{\eta_j}(x_{j,\mu_j})} \;\Big/\; \sum_{k=0}^{K_j} \frac{p_{j*j+1}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \tag{9}$$

   and then set x_{j*j+1} to x_{j,μ_j}.

3) Set μ_n to a value chosen uniformly at random from $\{0, \ldots, K_n\}$. (This selection has no effect on the estimate, but is used in the proof of correctness.)

4) Compute the estimate from this run as follows:

$$\hat{r}^{(i)}_{\rm LIS} \;=\; \prod_{j=0}^{n-1} \left[\frac{1}{K_j+1} \sum_{k=0}^{K_j} \frac{p_{j*j+1}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \;\Big/\; \frac{1}{K_{j+1}+1} \sum_{k=0}^{K_{j+1}} \frac{p_{j*j+1}(x_{j+1,k})}{p_{\eta_{j+1}}(x_{j+1,k})} \right] \tag{10}$$

(Note that most of the factors of $1/(K_j+1)$ and $1/(K_{j+1}+1)$ cancel, giving a final result of $(K_n+1)\,/\,(K_0+1)$, but the redundant factors are retained above for clarity of meaning.)

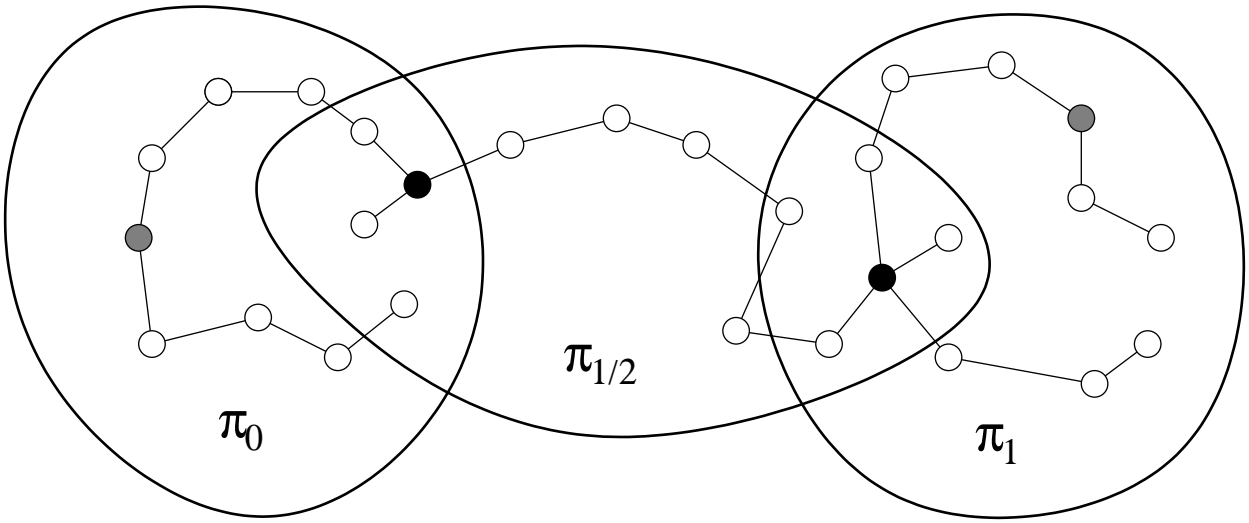

Figure 1: An illustration of Linked Importance Sampling. One intermediate distribution is used, with $\eta_1 = 1/2$. The distributions π_0, $\pi_{1/2}$, and π_1 are represented by ovals enclosing the regions of high probability under each distribution. Nine Markov chain transitions are performed at each stage. The two link states are shown as black dots. The initial and final states (indexed by ν_0 and μ_n) are shown as gray dots. Other states generated by the forward and reverse Markov chain transitions are shown as empty dots. For this run, $\nu_0 = 4$, $\mu_0 = 9$, $\nu_1 = 1$, $\mu_1 = 8$, $\nu_2 = 3$, and $\mu_2 = 7$.

The result of performing steps (1) through (3) is illustrated in Figure 1. After M runs of this procedure, the final estimate is computed as

$$\hat{r}_{\text{LIS}} \quad = \quad \frac{1}{M} \sum_{i=1}^{M} \hat{r}_{\text{LIS}}^{(i)} \tag{11}$$

The crucial aspect of Linked Importance Sampling is that when moving from distribution π_{η_j} to $\pi_{\eta_{j+1}}$, a link state, x_{j*j+1}, is randomly selected from among the sample of points $x_{j,1}, \ldots, x_{j,K_j+1}$ that are associated with π_{η_j}. We can view the link state as part of the sample associated with $\pi_{\eta_{j+1}}$ as well as that associated with π_{η_j}. Accordingly, when using the 'optimal' bridge of equation (6), I will set N_0/N_1 to $(K_j+1)/(K_{j+1}+1)$, though the proof of optimality for bridge sampling does not guarantee that this is an optimal choice when using this bridge distribution for LIS.

2.2 Proof that LIS estimates are unbiased

In order to prove that $\hat{r}_{\text{LIS}}^{(i)}$ is an unbiased estimate of $r = Z_1/Z_0$, we can regard steps (1) through (3) above as defining a distribution, Π_0, over all the quantities involved in the procedure — namely, x_j, μ_j, and ν_j, for $j = 0, \ldots, n$, with x_j representing $x_{j,0}, \ldots, x_{j,K_j}$. We then consider the procedure for generating these same quantities in reverse, which operates as follows:

The Reverse LIS Procedure

1) Pick an integer μ_n uniformly at random from $\{0, \ldots, K_n\}$, and then set x_{n,μ_n} to a value drawn from π_{η_n}.

2) For $j = n, \ldots, 0$, sample K_j+1 states drawn (at least approximately) from π_{η_j} as follows:

   a) If $j < n$: Pick an integer μ_j uniformly at random from $\{0, \ldots, K_j\}$, and then set x_{j,μ_j} to x_{j*j+1}.

   b) For $k = \mu_j + 1, \ldots, K_j$, draw $x_{j,k}$ according to the forward Markov chain transition probabilities $T_{\eta_j}(x_{j,k-1}, x_{j,k})$. (If $\mu_j = K_j$, do nothing in this step.)

   c) For $k = \mu_j - 1, \ldots, 0$, draw $x_{j,k}$ according to the reverse Markov chain transition probabilities $\underline{T}_{\eta_j}(x_{j,k+1}, x_{j,k})$. (If $\mu_j = 0$, do nothing in this step.)

   d) If $j > 0$: Pick a value for ν_j from $\{0, \ldots, K_j\}$ according to the following probabilities:

$$\Pi_1(\nu_j \,|\, x_j) \;=\; \frac{p_{j-1*j}(x_{j,\nu_j})}{p_{\eta_j}(x_{j,\nu_j})} \;\Big/\; \sum_{k=0}^{K_j} \frac{p_{j-1*j}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \tag{12}$$

   and then set x_{j-1*j} to x_{j,ν_j}.

3) Set ν_0 to a value chosen uniformly at random from $\{0, \ldots, K_0\}$.

This reverse procedure also defines a distribution over all the quantities generated (x_j, μ_j, and ν_j for $j = 0, \ldots, n$), which will be denoted by Π_1.

We now define the unnormalized probability (density) functions $P_0(x, \mu, \nu) = Z_0 \Pi_0(x, \mu, \nu)$ and $P_1(x, \mu, \nu) = Z_1 \Pi_1(x, \mu, \nu)$. The ratio of normalizing constants for these distributions is obviously $r = Z_1/Z_0$. We can estimate this ratio by simple importance sampling, using the ratios

$$\frac{P_1(x, \mu, \nu)}{P_0(x, \mu, \nu)} \;=\; \frac{Z_1 \, \Pi_1(\mu_n) \, \pi_{\eta_n}(x_{n,\mu_n}) \prod_{j=0}^{n-1} \Pi_1(\mu_j) \prod_{j=0}^{n} \Pi_1(x_j \,|\, \mu_j, x_{j,\mu_j}) \prod_{j=1}^{n} \Pi_1(\nu_j \,|\, x_j) \, \Pi_1(\nu_0)}{Z_0 \, \Pi_0(\nu_0) \, \pi_{\eta_0}(x_{0,\nu_0}) \prod_{j=1}^{n} \Pi_0(\nu_j) \prod_{j=0}^{n} \Pi_0(x_j \,|\, \nu_j, x_{j,\nu_j}) \prod_{j=0}^{n-1} \Pi_0(\mu_j \,|\, x_j) \, \Pi_0(\mu_n)} \tag{13}$$

From Steps (2b) and (2c) of the forward and reverse procedures, along with the mutual reversibility relationship of equation (8), we see that

$$\Pi_0(x_j \,|\, \nu_j, x_{j,\nu_j}) \;=\; \prod_{k=\nu_j+1}^{n} T_{\eta_j}(x_{j,k-1}, x_{j,k}) \;\cdot\; \prod_{k=0}^{\nu_j-1} \underline{T}_{\eta_j}(x_{j,k+1}, x_{j,k}) \tag{14}$$

$$= \prod_{k=\nu_j+1}^{n} T_{\eta_j}(x_{j,k-1}, x_{j,k}) \;\cdot\; \prod_{k=0}^{\nu_j-1} T_{\eta_j}(x_{j,k}, x_{j,k+1}) \, \frac{\pi_{\eta_j}(x_{j,k})}{\pi_{\eta_j}(x_{j,k+1})} \tag{15}$$

$$= \frac{\pi_{\eta_j}(x_{j,0})}{\pi_{\eta_j}(x_{j,\nu_j})} \prod_{k=1}^{n} T_{\eta_j}(x_{j,k-1}, x_{j,k}) \tag{16}$$

and similarly,

$$\Pi_1(x_j \,|\, \mu_j, x_{j,\mu_j}) \;=\; \frac{\pi_{\eta_j}(x_{j,0})}{\pi_{\eta_j}(x_{j,\mu_j})} \prod_{k=1}^{n} T_{\eta_j}(x_{j,k-1}, x_{j,k}) \tag{17}$$

From this, we see that parts of the ratio in equation (13) can be written as

$$\frac{Z_1\, \pi_{\eta_n}(x_{n,\mu_n}) \prod_{j=0}^{n} \Pi_1(x_j \,|\, \mu_j, x_{j,\mu_j})}{Z_0\, \pi_{\eta_0}(x_{0,\nu_0}) \prod_{j=0}^{n} \Pi_0(x_j \,|\, \nu_j, x_{j,\nu_j})} \;=\; \frac{p_{\eta_n}(x_{n,\mu_n})}{p_{\eta_0}(x_{0,\nu_0})} \prod_{j=0}^{n} \frac{\pi_{\eta_j}(x_{j,\nu_j})}{\pi_{\eta_j}(x_{j,\mu_j})} \;=\; \prod_{j=0}^{n-1} \frac{p_{\eta_{j+1}}(x_{j,\mu_j})}{p_{\eta_j}(x_{j,\mu_j})} \tag{18}$$

The last step uses the fact that for $j = 1, \ldots, n$, $x_{j,\nu_j} = x_{j-1*j} = x_{j-1,\mu_{j-1}}$.

From Steps (1) and (2a), we see that $\Pi_0(\nu_j) = 1\,/\,(K_j{+}1)$ and $\Pi_1(\mu_j) = 1\,/\,(K_j{+}1)$. Using this, and again using $x_{j,\nu_j} = x_{j-1,\mu_{j-1}}$, we get that

$$\frac{\prod_{j=0}^{n-1} \Pi_1(\mu_j) \prod_{j=1}^{n} \Pi_1(\nu_j \,|\, x_j)}{\prod_{j=1}^{n} \Pi_0(\nu_j) \prod_{j=0}^{n-1} \Pi_0(\mu_j \,|\, x_j)} \;=\; \frac{\prod_{j=0}^{n-1} \Pi_1(\nu_{j+1} \,|\, x_{j+1})\,(K_{j+1}{+}1)}{\prod_{j=0}^{n-1} \Pi_0(\mu_j \,|\, x_j)\,(K_j{+}1)} \tag{19}$$

$$= \prod_{j=0}^{n-1} \frac{\dfrac{p_{j*j+1}(x_{j+1,\nu_{j+1}})}{p_{\eta_{j+1}}(x_{j+1,\nu_{j+1}})} \Big/ \dfrac{1}{K_{j+1}{+}1} \displaystyle\sum_{k=0}^{K_{j+1}} \dfrac{p_{j*j+1}(x_{j+1,k})}{p_{\eta_{j+1}}(x_{j+1,k})}}{\dfrac{p_{j*j+1}(x_{j,\mu_j})}{p_{\eta_j}(x_{j,\mu_j})} \Big/ \dfrac{1}{K_j{+}1} \displaystyle\sum_{k=0}^{K_j} \dfrac{p_{j*j+1}(x_{j,k})}{p_{\eta_j}(x_{j,k})}} \tag{20}$$

$$= \prod_{j=0}^{n-1} \frac{p_{\eta_j}(x_{j,\mu_j})}{p_{\eta_{j+1}}(x_{j,\mu_j})} \prod_{j=0}^{n-1} \left[\frac{1}{K_j{+}1} \sum_{k=0}^{K_j} \frac{p_{j*j+1}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \Big/ \frac{1}{K_{j+1}{+}1} \sum_{k=0}^{K_{j+1}} \frac{p_{j*j+1}(x_{j+1,k})}{p_{\eta_{j+1}}(x_{j+1,k})} \right] \tag{21}$$

From Steps (1) and (3), we see that $\Pi_0(\nu_0) = \Pi_1(\nu_0) = 1\,/\,(K_0{+}1)$ and $\Pi_1(\mu_n) = \Pi_0(\mu_n) = 1\,/\,(K_n{+}1)$, so these factors cancel in equation (13). The factors in equation (18) cancel with the first part of equation (21). The final result is that the simple importance sampling estimate based on a single LIS run is as shown in equation (10), demonstrating that $\hat{r}_{\text{LIS}}$ is indeed an unbiased estimate of $r = Z_1/Z_0$.

2.3 Bridged LIS estimates

Since the LIS estimate can be viewed as a simple importance sampling estimate on an extended space, we can consider a 'bridged LIS' estimate in which this top-level SIS estimate is replaced by a bridge sampling estimate. This will require that we actually perform the reverse LIS procedure described above, from which an LIS estimate for the reverse ratio, $\underline{r} = Z_0/Z_1$, can be computed:

$$\hat{\underline{r}}^{(i)}_{\text{LIS}} \;=\; \prod_{j=1}^{n} \left[\frac{1}{K_j + 1} \sum_{k=0}^{K_j} \frac{p_{j-1*j}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \Big/ \frac{1}{K_{j-1} + 1} \sum_{k=0}^{K_{j-1}} \frac{p_{j-1*j}(x_{j-1,k})}{p_{\eta_{j-1}}(x_{j-1,k})} \right] \tag{22}$$

The reversed procedure requires independent sampling from π_1. This will usually not be possible directly, but well-separated states from a Markov chain sampler with π_1 as its invariant distribution will provide a good approximation, provided that this sampler moves around the whole distribution, without being trapped in an isolated mode. Indeed, the entire sample of K_n+1 states from π_1 that is needed at the start of the reverse procedure can be obtained by taking consecutive states from such a Markov chain sampler.

For the bridged form of LIS, we also need a suitable bridge distribution, P_*, for which we must be able to evaluate the ratios P_*/P_0 and P_*/P_1. (Note that this choice of a 'top-level' bridge distribution is separate from the choices of 'low-level' bridge distributions, p_{j*j+1}, though we might use the same form for both.) With the optimal bridge of equation (6), these ratios can be written as follows, if the forward procedure is performed M times and the reverse procedure $\underline{M}$ times:

$$\frac{P_*^{\text{opt}}(x,\mu,\nu)}{P_0(x,\mu,\nu)} = \left[r\,(M/\underline{M}) \left(\frac{P_1(x,\mu,\nu)}{P_0(x,\mu,\nu)}\right)^{-1} + 1 \right]^{-1} \tag{23}$$

$$\frac{P_*^{\text{opt}}(x,\mu,\nu)}{P_1(x,\mu,\nu)} = \left[r\,(M/\underline{M}) + \left(\frac{P_0(x,\mu,\nu)}{P_1(x,\mu,\nu)}\right)^{-1} \right]^{-1} \tag{24}$$

The geometric bridge of equation (5) results in

$$\frac{P_*^{\text{geo}}(x,\mu,\nu)}{P_0(x,\mu,\nu)} = \sqrt{\frac{P_1(x,\mu,\nu)}{P_0(x,\mu,\nu)}} \tag{25}$$

$$\frac{P_*^{\text{geo}}(x,\mu,\nu)}{P_1(x,\mu,\nu)} = \sqrt{\frac{P_0(x,\mu,\nu)}{P_1(x,\mu,\nu)}} \tag{26}$$

These expressions allow us to express bridged LIS estimates in terms of the simple LIS estimate of equation (10), and its reverse version of equation (22). For the optimal bridge, we get

$$\hat{r}^{\text{opt}}_{\text{LIS-bridged}} = \frac{1}{M}\sum_{i=1}^{M} \frac{1}{r\,(M/\underline{M})\,/\,\hat{r}^{(i)}_{\text{LIS}} + 1} \Big/ \frac{1}{\underline{M}}\sum_{i=1}^{\underline{M}} \frac{1}{r\,(M/\underline{M}) + 1/\underline{\hat{r}}^{(i)}_{\text{LIS}}} \tag{27}$$

Similarly, for the geometric bridge, we get

$$\hat{r}^{\text{geo}}_{\text{LIS-bridged}} = \frac{1}{M}\sum_{i=1}^{M} \sqrt{\hat{r}^{(i)}_{\text{LIS}}} \Big/ \frac{1}{\underline{M}}\sum_{i=1}^{\underline{M}} \sqrt{\underline{\hat{r}}^{(i)}_{\text{LIS}}} \tag{28}$$

2.4 LIS estimates with independent sampling with no intermediate distributions

It is interesting to look at the special case of Linked Importance Sampling with $n = 1$ — ie, in which the are no intermediate distributions between π_0 and π_1 — in which the points from both π_0 and π_1 are sampled independently. The LIS procedure can then be simplified somewhat, and it is also possible to improve the LIS estimate by averaging over the choice of link state. Such averaging is not

feasible when Markov chain sampling is used, since choosing a different link state would require a new simulation of the Markov transitions.

Since we will sample points independently, there is no need to decide how many points will be sampled by the forward transitions and how many by the reverse transitions in Steps (2a) and (2b) of the LIS procedure. We simply obtain a pair of samples consisting of points $x_{0,0}, \ldots, x_{0,K_0}$ drawn independently from π_0, and points $x_{1,1}, \ldots, x_{1,K_1}$ drawn independently from π_1. We then randomly select a link state, indexed by μ, from among $x_{0,0}, \ldots, x_{0,K_0}$ according to the following probabilities, which depend on the choice of a single bridge distribution, denoted by $p_*(x)$:

$$\Pi_0(\mu \,|\, x_0) \;=\; \frac{p_*(x_{0,\mu})}{p_0(x_{0,\mu})} \;\Big/\; \sum_{k=0}^{K_0} \frac{p_*(x_{0,k})}{p_0(x_{0,k})} \tag{29}$$

The LIS estimate for $r = Z_1/Z_0$ based on this pair of samples from π_0 and π_1 is

$$\hat{r}^{(i)}_{\text{LIS}} \;=\; \frac{1}{K_0+1} \sum_{k=0}^{K_0} \frac{p_*(x_{0,k})}{p_0(x_{0,k})} \;\Big/\; \frac{1}{K_1+1} \left[\frac{p_*(x_{0,\mu})}{p_1(x_{0,\mu})} + \sum_{k=1}^{K_1} \frac{p_*(x_{1,k})}{p_1(x_{1,k})} \right] \tag{30}$$

The superscript i is used here to indicate that this estimate is based on the i'th pair of samples. We can see that it is very similar to the bridge sampling estimate of equation (4), except that the link state is included in both samples. Since these LIS estimates are unbiased, we can average M of them to obtain a final LIS estimate.

We can also average the estimate of equation (30) over the random choice of link state, which is guaranteed to produce an estimate (also unbiased) with smaller mean-squared-error (see Schervish 1995, Section 3.2). The result is

$$\hat{r}^{(i)}_{\text{LIS-ave}} \;=\; \sum_{\mu=0}^{K_0} \Pi_0(\mu \,|\, x_0) \; \frac{1}{K_0+1} \sum_{k=0}^{K_0} \frac{p_*(x_{0,k})}{p_0(x_{0,k})} \;\Big/\; \frac{1}{K_1+1} \left[\frac{p_*(x_{0,\mu})}{p_1(x_{0,\mu})} + \sum_{k=1}^{K_1} \frac{p_*(x_{1,k})}{p_1(x_{1,k})} \right] \tag{31}$$

$$\;=\; \frac{K_1+1}{K_0+1} \sum_{\mu=0}^{K_0} \frac{p_*(x_{0,\mu})}{p_0(x_{0,\mu})} \;\Big/\; \left[\frac{p_*(x_{0,\mu})}{p_1(x_{0,\mu})} + \sum_{k=1}^{K_1} \frac{p_*(x_{1,k})}{p_1(x_{1,k})} \right] \tag{32}$$

Averaging these estimates over M pairs of samples produces a final estimate denoted by $\hat{r}_{\text{LIS-ave}}$.

To use bridged LIS in this context, we need to find reverse estimates as well, but these reverse estimates needn't be independent of the forward estimates, since the asymptotic validity of the bridge sampling estimate of equation (4) does not depend on the samples x_0 and x_1 being independent. Accordingly, we can use the same samples from π_0 and π_1 for the forward and the reverse operations. However, to perform reverse sampling, we need to have a sample of K_1+1 points drawn from π_1, the first of which is ignored when performing forward sampling. Conversely, the first of the K_0+1 points drawn from π_0 is ignored when performing the reverse sampling.

We can improve the bridged LIS estimates by averaging the numerator and the denominator of equation (27) or (28) with respect to the random choice of link state. We can also average with

respect to the omission of one of the points from one of the samples — ie, rather than omitting the first of $K_1 + 1$ points in the sample from π_1 when computing a forward estimate, we average with respect to a random choice of point to omit, and similarly for reverse estimates. Note that the averaging should be done over the sums in the numerator and denominator, not with respect to the entire estimate, nor with respect to the values of $\hat{r}^{(i)}_{\text{LIS}}$ and $\underline{\hat{r}}^{(i)}_{\text{LIS}}$ appearing inside the summands. The effective sample size after this additional averaging of dependent points is unclear, so it is not obvious what the ratio of sample sizes in equation (6) should be, but using $(K_0+1)/(K_1+1)$ is probably adequate.

3 Analytical comparisons of AIS and LIS

In this section, I analyse (somewhat informally) the performance of AIS and LIS asymptotically, and in other situations where analytical results are possible.

3.1 Asymptotic properties of AIS and LIS estimates

I begin by analysing the asymptotic performance of AIS and LIS when the sequence of distributions is defined by an unnormalized density function of the following form:

$$p_\eta(x) \quad = \quad p_0(x) \, \exp(-\eta U(x)) \tag{33}$$

This class includes sequences of canonical distributions defined by equation (1) in which the inverse temperature varies, as well as sequences that can be used for Bayesian analysis, in which p_0 defines the prior and η is a power that the likelihood (expressed as $\exp(-U(x))$) is raised to, with $\eta = 1$ giving the posterior distribution. For these distributions, we can express r using the well-known 'thermodynamic integration' formula as follows:

$$r \quad = \quad \log(Z_1/Z_0) \quad = \quad -\int_0^1 E_{\pi_\eta}(U) \, d\eta \tag{34}$$

The analysis here is asymptotic, as the number of intermediate distributions used, given by $n-1$, goes to infinity. I will assume the η_j defining these distributions are chosen according to a scheme in which for any $a \in (0,1)$, the spacing $\eta_{j+1} - \eta_j$ when $j = \lfloor a\, n \rfloor$ is asymptotically proportional to $1/n$ — in other words, the relative density of intermediate distributions in the neighborhood of different values of η stays the same as the overall density increases. The simplest such scheme is to let $\eta_j = j/n$, though other schemes may sometimes be better.

With the above form for p_η, the AIS estimate from a single run (from equation (7)) can be written as follows:

$$\log \, \hat{r}^{(i)}_{\text{AIS}} \quad = \quad \sum_{j=0}^{n-1} \log \left(p_{\eta_{j+1}}(x_j^{(i)}) \Big/ p_{\eta_j}(x_j^{(i)}) \right) \quad = \quad \sum_{j=0}^{n-1} -(\eta_{j+1} - \eta_j) \, U\left(x_j^{(i)}\right) \tag{35}$$

When $\eta_j = j/n$, this can be seen as a stochastic form of Riemann's Rule for numerically integrating equation (34), though one difference is that $\log\ \hat{r}_{\text{AIS}}$ converges to the correct value as M goes to infinity even if n stays fixed.

Provided that there is some finite bound on the variance of U under all the distributions π_η, and that the Markov transitions used mix well, a Central Limit Theorem will apply, allowing us to conclude that the distribution of $\ell_n = \log\ \hat{r}^{(i)}_{\text{AIS}}$ becomes Gaussian as n goes to infinity. Let the mean of ℓ_n be μ_n, and let the variance of ℓ_n asymptotically be σ^2/n, where σ is determined by details of the spacing of intermediate distributions and of the degree of autocorrelation in the Markov transitions. Note that $E[Y^q] = \exp(q\mu + q^2\varsigma^2/2)$ when $Y = \exp(X)$ and X is Gaussian with mean μ and variance ς^2. Using this, the mean of $\exp(\ell_n)$ is $\exp(\mu_n + \sigma^2/2n)$. This must equal r, since $\hat{r}_{\text{AIS}}$ is unbiased, so $\mu_n = \log(r) - \sigma^2/2n$. Using this, we can see that the variance of $\hat{r}^{(i)}_{\text{AIS}} = \exp(\ell_n)$ is $r\,[\exp(\sigma^2/2n) - 1]$, which for large n will be approximately $r\sigma^2/2n$. The variance of $\hat{r}_{\text{AIS}}$ will therefore be $r\sigma^2/2nM$. Asymptotically, the total computational effort, which will generally be proportional to nM, can be divided in any way between more intermediate distributions (n) or more runs (M) without affecting the accuracy of estimation of r, provided that n is kept large enough that these asymptotic results apply — a fact noted by Hendrix and Jarzynski (2001). We can therefore use a value of M greater than one without penalty, in order to obtain an error estimate from the degree of variation over the M runs.

For LIS, we can write the log of the estimate from one run (equation (10)) as follows:

$$\log\ \hat{r}^{(i)}_{\text{LIS}} \;=\; \sum_{j=0}^{n-1} \left[\log\left(\frac{1}{K_j+1} \sum_{k=0}^{K_j} \frac{p_{j*j+1}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \right) \;-\; \log\left(\frac{1}{K_{j+1}+1} \sum_{k=0}^{K_{j+1}} \frac{p_{j*j+1}(x_{j+1,k})}{p_{\eta_{j+1}}(x_{j+1,k})} \right) \right] \tag{36}$$

Suppose that we let $K_j = \lceil mK_j^0 \rceil$ for all j and some set of K_j^0, and that we then let m go to infinity. Assuming that the variances of the ratios of probabilities are finite, and that the Markov chain transitions used mix sufficiently well, a Central Limit Theorem will again apply, and we can conclude that all of the n terms in the sum above, and therefore also the sum itself, will approach Gaussian distributions, with variances proportional to $1/m$.

To analyse the LIS estimate in more detail, we need to assume a form of bridge distribution, as well as a form for p_η. If p_η has the form of equation (33) and we use the geometric bridge of equation (5), we can write

$$\begin{aligned} \log\ \hat{r}^{(i)}_{\text{LIS}} \;=\; \sum_{j=0}^{n-1} \Bigg[& \log\left(\frac{1}{K_j+1} \sum_{k=0}^{K_j} \exp(-(\eta_{j+1}-\eta_j)\,U(x_{j,k})\,/\,2) \right) \;- \\ & \log\left(\frac{1}{K_{j+1}+1} \sum_{k=0}^{K_j} \exp(-(\eta_j-\eta_{j+1})\,U(x_{j+1,k})\,/\,2) \right) \Bigg] \end{aligned} \tag{37}$$

Since $\exp(z) \approx 1 + z$ and $\log(1+z) \approx z$ when z is small, we can rewrite this when n is large (and

hence $\eta_{j+1}-\eta_j$ is small) as

$$\log\ \hat{r}_{\mathrm{LIS}}^{(i)} \approx \sum_{j=0}^{n-1} \left[\log\left(1 - \frac{\eta_{j+1}-\eta_j}{2} \frac{1}{K_j+1} \sum_{k=0}^{K_j} U(x_{j,k})\right) - \log\left(1 + \frac{\eta_{j+1}-\eta_j}{2} \frac{1}{K_{j+1}+1} \sum_{k=0}^{K_{j+1}} U(x_{j+1,k})\right) \right] \tag{38}$$

$$\approx \sum_{j=0}^{n-1} -\frac{\eta_{j+1}-\eta_j}{2} \left[\frac{1}{K_j+1} \sum_{k=0}^{K_j} U(x_{j,k}) + \frac{1}{K_{j+1}+1} \sum_{k=0}^{K_{j+1}} U(x_{j+1,k}) \right] \tag{39}$$

$$= -\frac{\eta_1-\eta_0}{2} \frac{1}{K_0+1} \sum_{k=0}^{K_0} U(x_{0,k}) - \frac{\eta_n-\eta_{n-1}}{2} \frac{1}{K_n+1} \sum_{k=0}^{K_n} U(x_{n,k}) - \sum_{j=1}^{n-1} \frac{\eta_{j+1}-\eta_{j-1}}{2} \frac{1}{K_j+1} \sum_{k=0}^{K_j} U(x_{j,k}) \tag{40}$$

When $\eta_j = j/n$, this looks like a stochastic form of the Trapezoidal Rule for numerically integrating equation (34). Since the Trapezoidal Rule converges faster than Reimann's Rule, one might expect LIS to perform better than AIS asymptotically, but this is not so in this stochastic situation. Suppose for simplicity that we set all $K_j = m$. The variance of $\log\ \hat{r}_{\mathrm{LIS}}^{(i)}$ will be dominated by the variance of the last sum above, which will be proportional to $1/nm$, assuming that m is large, so that the dependence between terms (from sharing link states) is negligible. Using the same argument as for AIS above, the variance of $\log \hat{r}_{\mathrm{LIS}}$ will be proportional to $1/nmM$. Considering that the computation time for an LIS run will be proportional to nm, versus n for AIS, we see that the variances of the AIS and LIS estimates go down the same way in proportion to computation time, asymptotically as n and m go to infinity.

Furthermore, the proportionality constant should be the same for AIS and LIS, assuming that the overhead of the two procedures is negligible compared to the time spent performing Markov transitions, so that the proportionality constants for computation time are the same for AIS (multiplying n) and for LIS (multiplying nm). The proportionality constants for variance for AIS (multiplying $1/nM$) and for LIS (multiplying $1/nmM$) depend in a complex way on the form of the density of η_j values and on the mixing properties of the Markov transitions, but the result should be the same for AIS and LIS, provided the same scheme is used for choosing η_j values, and the same Markov transitions are used, parameterized smoothly in terms of η. A difference that might appear significant is that for AIS only one Markov transition is done for each η_j, whereas for LIS, m such transitions are done. However, as n goes to infinity, nearby distributions become more similar, so transitions for m consecutive distributions become similar to m transitions for one of these distributions.

The apparently pessimistic conclusion from this is that when both n and m (and hence the K_j) are large, the performance of LIS should be about the same as that of AIS (with n for AIS chosen to

equalize the computation time), assuming that the distributions used have the form of equation (33), that the variance of U is finite under all of the distributions π_η, and that the Markov transitions used mix well enough. Fortunately, however, there is no reason to make both m and n large with LIS. For good performance, n must be large enough that π_{η_j} and $\pi_{\eta_{j+1}}$ overlap significantly, but there is no reason to make n much larger than this. The accuracy of the estimates can be improved as desired by increasing m and/or M while keeping n fixed. The results below show that LIS estimates with n fixed are sometimes much better than AIS estimates.

Finally, let us consider the asymptotic performance of the bridged versions of AIS and LIS, assuming that the variance of U is finite, so that the distribution of the estimates from individual runs becomes Gaussian as n (for AIS) or m (for LIS) goes to infinity. Looking at equations (27) and (28), which also are applicable to bridged AIS estimates, we see that the log of $\hat{r}^{(i)}_{\text{LIS-bridged}}$ can for both optimal and geometric bridges be expressed as the difference of the log of the numerator, which is the mean of a function of the forward estimates, $\hat{r}^{(i)}_{\text{LIS}}$, and the log of the denominator, which is the mean of a function of the reverse estimates, $\underline{\hat{r}}^{(i)}_{\text{LIS}}$. If these forward and reverse estimates have Gaussian distributions with small variances, σ^2 and $\underline{\sigma}^2$, then $\hat{r}^{(i)}_{\text{LIS-bridged}}$ will also be Gaussian, with a variance that can be computed in terms of the derivatives of the summands in the numerator and the denominator, with respect to $\hat{r}^{(i)}_{\text{LIS}}$ and $\underline{\hat{r}}^{(i)}_{\text{LIS}}$, evaluated at the true values of r and $1/r$. I will assume that $r = 1$ below, as can be done without loss of generality.

For the geometric bridge, these derivatives are both $1/2$, from which it follows that the variance of the numerator in equation (28) is $\sigma^2/4M$ and that of the denominator is $\underline{\sigma}^2/4\underline{M}$. Since the numerator and denominator evaluate to one for $\hat{r}^{(i)}_{\text{LIS}} = r = 1$ and $\underline{\hat{r}}^{(i)}_{\text{LIS}} = 1/r = 1$, the sum of the variances of the logs of the numerator and denominator is $\sigma^2/4M + \underline{\sigma}^2/4\underline{M}$. If $\sigma^2 = \underline{\sigma}^2$ and $M = \underline{M}$, this reduces to $\sigma^2/2M$. The variance of an unbridged LIS estimate will be σ^2/M. However, the bridged estimate requires time proportional to $M + \underline{M}$, compared to just M for the unbridged estimate. The value of M for the unbridged method can therefore be twice as large as for the bridged method, with the result that bridged and unbridged estimates perform equally well asymptotically (assuming the variance of U is finite).

For the optimal bridge, the derivatives of the summands in the numerator and denominator are both $1/4$, when evaluated at $\hat{r}^{(i)}_{\text{LIS}} = r = 1$ and $\hat{r}^{(i)}_{\text{LIS}} = 1/r = 1$, and assuming that $M = \underline{M}$. The numerator and denominator both evaluate to $1/2$, with the result that asymptotically the variance of the bridged estimate, assuming $\sigma^2 = \underline{\sigma}^2$, is $\sigma^2/2M$, the same as for the geometric bridge.

In conclusion, bridged AIS and LIS estimates asymptotically have the same performance as the corresponding unbridged estimates (with twice the value of M), for both the optimal and geometric bridges, assuming U has finite variance. This conclusion applies more generally, as long as a Central Limit Theorem holds for the individual estimates, $\hat{r}^{(i)}_{\text{LIS}}$ and $\underline{\hat{r}}^{(i)}_{\text{LIS}}$. However, the bridged methods may be much better when the variance of U is infinite, or for classes of distributions other than that of equation (33). The bridged methods may also provide improvement when the values of n or m are not large enough for the asymptotic results to apply.

3.2 Properties of AIS and LIS when sampling from uniform distributions

In this section, I will demonstrate that when n is kept suitably small, LIS can perform much better than AIS when these methods are applied to sequences of uniform distributions.

As a first example, consider the class of nested uniform distributions with unnormalized densities given by

$$p_\eta(x) \;=\; \begin{cases} 1 & \text{if } -s^\eta < x < s^\eta \\ 0 & \text{otherwise} \end{cases} \tag{41}$$

for which the normalizing constants are $Z_\eta = 2s^\eta$, so that $r = Z_1/Z_0 = s$. The results concerning this class of distributions can easily be extended to any class of uniform distributions, in any number of dimensions, that have nested regions of support. For both AIS and LIS, I will assume that the intermediate distributions are defined by $\eta_j = j/n$. With this choice, the probability that a point, x, randomly sampled from π_j will have $p_{j+1}(x) = 1$ is $s^{1/n}$, for any j.

During an AIS run, only a single point is sampled from each distribution. An AIS run will produce an estimate for r of zero if any of the ratios $p_{\eta_{j+1}}(x_j^{(i)}) \,/\, p_{\eta_j}(x_j^{(i)})$ in equation (7) are zero, which happens with probability $1 - (s^{1/n})^n = 1 - s$, and will otherwise produce an estimate of one. Note that the distribution of estimates is independent of n. AIS is therefore not a useful technique for nested uniform distributions — simple importance sampling (ie, AIS with $n=1$) would work just as well (or just as poorly, if s is very small). Bridged AIS produces no improvement in this context.

Suppose instead we use LIS with all $K_j = m$, and suppose that the Markov transitions, T_j, produce points that are almost independent of the previous point. For this problem, both the geometric and optimal forms of the bridge distribution result in $p_{j*j+1}(x) = p_{\eta_{j+1}}(x)$. If $m+1$ points are sampled independently from π_{η_j}, the fraction of these points for which $p_{\eta_{j+1}}(x)$ is one will have variance $s^{1/n}\,(1-s^{1/n}) \,/\, (m+1)$. For sufficiently large m, the variance of the log of this fraction will be approximately $(s^{1/n}\,(1-s^{1/n}) \,/\, (m+1)) \,/\, s^{2/n}$, which simplifies to $(s^{-1/n}-1) \,/\, (m+1)$. For this approximation to be useful, the probability that none of the $m+1$ points sampled from π_{η_j} lie in the region where $p_{\eta_{j+1}}$ is one, equal to $(1-s^{1/n})^{m+1}$, must be negligible. This probability must be fairly small anyway, if LIS is to perform well.

Suppose that the computational cost of an LIS run is proportional to the sum of the number of points sampled from π_0 and the number of Markov transitions performed. If we fix this cost, the number of intermediate distributions, n, and the number of transitions for each distribution, m, will be related by $m(n+1) \;=\; C$, for some constant C. Assume for the moment that both n and m are large. The probability of a run producing a zero estimate will then be negligible, and we can assess the accuracy of the estimate for one run by the variance of $\log \hat{r}_{\text{LIS}}^{(i)}$ (modified in some way to eliminate the infinity resulting from the negligible, but non-zero, probability that $\hat{r}_{\text{LIS}}^{(i)}$ is zero). Looking at equation (36), we see that for these nested uniform distributions, the second log term vanishes — $p_{j*j+1}(x_{j+1,k}) \,/\, p_{\eta_{j+1}}(x_{j+1,k})$ is always one, since p_{j*j+1} is the same as $p_{\eta_{j+1}}$. When m is large, the dependence between terms with different values of j will be negligible, so we can add the variances of

the terms to get the variance of the estimate, obtaining the result that

$$\mathrm{Var}\Big(\log\ \hat{r}^{(i)}_{\mathrm{LIS}}\Big) \quad \approx \quad n\,(s^{-1/n}-1)\,/\,(m+1) \tag{42}$$

When n is large, $s^{-1/n} = \exp(\log(1/s)/n)$ is approximately $1 + \log(1/s)/n$, and hence the variance above is approximately $\log(1/s)\,/\,(m+1)$. So it seems that the larger the value of m, the better — until we reach a value of m for which the corresponding value of n, equal to $C/m - 1$, is small enough that this result no longer applies.

Best performance will therefore come using a fairly small value of n, but a large value of m. Substituting $m = C/(n+1)$ into equation (42), and assuming $m/(m+1) \approx 1$, we get

$$\mathrm{Var}\Big(\log\ \hat{r}^{(i)}_{\mathrm{LIS}}\Big) \quad \approx \quad n\,(s^{-1/n}-1)\,/\,(C/(n+1)) \quad = \quad n(n+1)\,(s^{-1/n}-1)\,/\,C \tag{43}$$

The value of n that minimizes this depends only on s, not on C. The optimal choice of n increases slowly as s gets smaller: $s = 0.1$ gives $n = 2$, $s = 0.05$ gives $n = 3$, $s = 0.01$ gives $n = 4$, and $s = 0.0001$ gives $n = 7$.

As a second example, consider the class of non-nested uniform distributions with unnormalized densities given by

$$p_\eta(x) \quad = \quad \begin{cases} 1 & \text{if } \eta t - 1 < x < \eta t + 1 \\ 0 & \text{otherwise} \end{cases} \tag{44}$$

For this class, $Z_\eta = 2$ for all η, so $r = Z_1/Z_0 = 1$. I will again assume that the intermediate distributions are defined by $\eta_j = j/n$, and that all $K_j = m$. Assuming that n is greater than $t/2$, the probability that a point, x, randomly sampled from π_{η_j} will have $p_{\eta_{j+1}}(x) = 1$ is $1 - t/2n$, for any j.

For this example, AIS estimates do not converge to the true value of r as M increases, regardless of the value of n. To see this, note that the ratios in equation (7) will all be either zero or one, and that the estimate from one run, $\hat{r}^{(i)}_{\mathrm{AIS}}$, will be one if all of these ratios are one, and zero otherwise. The probability of a particular ratio being one is $1 - t/2n$, so the probability that all are one (assuming the T_η produce points independent of the current point) is $(1 - t/2n)^n$, which approaches $\exp(-t/2)$ as n goes to infinity. The AIS estimate, averaging over M runs, will have mean $\exp(-t/2)$, rather than the correct value of one.

In contrast, bridged AIS estimates will converge to the true value as M increases, as long as n is at least $t/2$, so that there is overlap between successive distributions in the sequence. However, when t is large, the overlap between the distributions over paths produced by forward and reverse AIS runs, given by $\exp(-t/2)$, will be very small, and the procedure will be very inefficient.

To see how well LIS performs, recall the formula for $\log \hat{r}_{\mathrm{LIS}}$ from equation (36):

$$\log\ \hat{r}^{(i)}_{\mathrm{LIS}} \quad = \quad \sum_{j=0}^{n-1} \left[\log \left(\frac{1}{K_j+1} \sum_{k=0}^{K_j} \frac{p_{j*j+1}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \right) \ - \ \log \left(\frac{1}{K_{j+1}+1} \sum_{k=0}^{K_{j+1}} \frac{p_{j*j+1}(x_{j+1,k})}{p_{\eta_{j+1}}(x_{j+1,k})} \right) \right] \tag{45}$$

Due to symmetry, the two log terms above have the same distribution, for all j. The variance of one of these log terms (for large m) is $((t/2n)\,(1-t/2n)\,/\,(m+1))\,/\,(1-t/2n)^2$, which simplifies to $1\,/\,((2n/t-1)\,(m+1))$. The second log term in equation (36) for one j will involve the same points, $x_{j+1,k}$, as the first log term for the next j. The effect of this is that these terms will be negatively correlated, with correlation of -1 if $n=t$. However, since the two terms occur with opposite signs, the effect on the final sum is that $n-1$ pairs of terms (out of $2n$ terms total) are positively correlated. Straightforward calculations show that this correlation is $2n/t-1$ for $t/2 < n \le t$ and $1\,/\,(2n/t-1)$ for $n \ge t$. Using the fact that when X and Y have the same distribution, $\mathrm{Var}(X+Y) = 2\,\mathrm{Var}(X)\,[1+\mathrm{Cor}(X,Y)]$, we obtain the result that, for large m,

$$\mathrm{Var}\Big(\log\ \hat{r}^{(i)}_{\mathrm{LIS}}\Big) \;\approx\; \frac{2}{(2n/t-1)\,(m+1)} \left\{ \begin{array}{ll} n\ +\ (n-1)\,(2n/t-1) & \text{if } t/2 < n \le t \\ n\ +\ (n-1)\,/\,(2n/t-1) & \text{if } n \ge t \end{array} \right\} \tag{46}$$

Setting $m = C/(n+1)$, and assuming $m/(m+1) \approx 1$, gives

$$\mathrm{Var}\Big(\log\ \hat{r}^{(i)}_{\mathrm{LIS}}\Big) \;\approx\; \frac{2(n+1)}{C(2n/t-1)} \left\{ \begin{array}{ll} n\ +\ (n-1)\,(2n/t-1) & \text{if } t/2 < n \le t \\ n\ +\ (n-1)\,/\,(2n/t-1) & \text{if } n \ge t \end{array} \right\} \tag{47}$$

Numerical investigation shows that the global minimum of the variance occurs where n is near $(3/2)\,t$. A second local minimum where n is near $(3/4)\,t$ also exists. The two minima are nearly equally good when t is large. There is a local maximum where n is near t, with the variance there being about 19% greater than at the global minimum. The variance is much larger for very large and very small values of n. We therefore see that for this example too, the best results are obtained by fixing n to a moderate value; any desired level of accuracy can then be obtained by increasing m and/or M.

4 Empirical comparisons of AIS and LIS

The analytical results of the previous section indicate that LIS can sometimes perform much better than AIS, but that the benefits of LIS may only be seen when the number of intermediate distributions used is kept suitably small (but not so small that they do not overlap). In this section, I investigate the performance of AIS and LIS (and their bridged versions) empirically. The programs used for these tests (written in R) are available from my web page.

These tests were done using sequences of one-dimensional distributions having unnormalized density functions of the following form:

$$p_\eta(x) \;=\; \exp\Big(-\Big|(x-\eta t)\,/\,s^\eta\Big|^q\Big) \tag{48}$$

where s, t, and q are fixed constants. As η moves from 0 to 1, the centre of this distribution shifts by t, and changes width by the factor s. The power q controls how thick the tails of the distributions are. When $q = 2$, the distributions are Gaussian; a larger value produces lighter tails. Note that Z_η is proportional to s^η, and hence $r = Z_1/Z_0$ is equal to s.

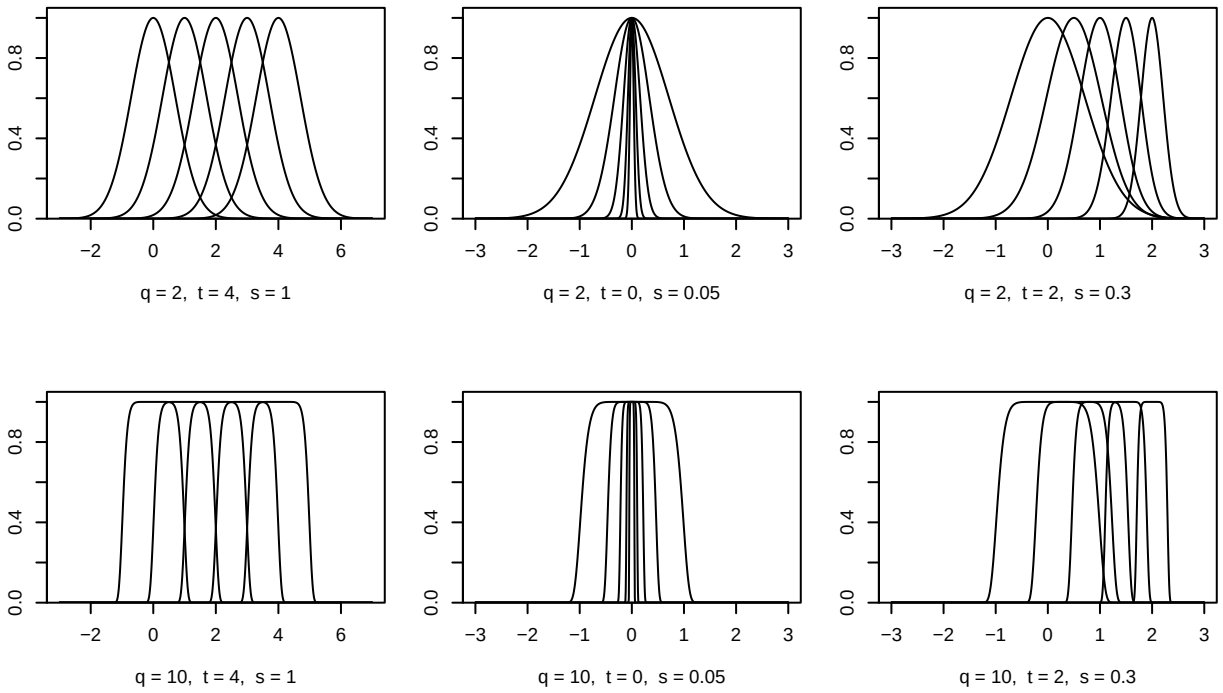

Figure 2: The sequences of unnormalized density functions used for the tests. The plots show the unnormalized density functions for $\eta = 0, 1/4, 2/4, 3/4, 1$, for six combinations of s, t, and q.

If $t = 0$, the distributions can be written in the form of equation (33), after reparameterizing in terms of $\eta' = 1/s^{\eta q}$, so that $p_{\eta'}(x) = \exp(-\eta'|x|^q)$. In this case, we expect the asymptotic behaviour to be as discussed in Section 3.1, but the behaviour with samples of practical size may be different. As q goes to infinity, the distributions converge to uniform distributions over $(\eta t - s^\eta, \eta t + s^\eta)$, and the results of Section 3.2 become relevant.

I did an initial set of tests using six sequences of distributions. Three of these sequences were of Gaussian distributions, with $q = 2$. The first of these used $s = 1$ and $t = 4$, producing a shift with no change in scale as η increases from 0 to 1. The second used $s = 0.05$ and $t = 0$, producing a contraction with no shift. The last used $s = 0.3$ and $t = 2$, combining a shift with a contraction. A second set of three sequences used the same values of s and t, but with $q = 10$, which produces more 'rectangular' distributions with lighter tails. The six sequences are shown in Figure 2. Each sequence in these plots consists of five distributions, corresponding to $\eta = 0, 1/4, 2/4, 3/4, 1$. These were the sequences used for the LIS runs (hence $n = 4$ for these runs). The AIS runs used more distributions, spaced more finely with respect to η, so as to produce the same number of Markov transitions and sampling operations as in the LIS runs.

These distributions (for any η) can easily be sampled from using rejection sampling. Samples from π_0 and π_1 were used to initialize forward and reverse runs of AIS and LIS. For this test, we pretend that sampling for other π_η must be done using Markov chain methods. The transition used for π_η, T_η, was a random-walk Metropolis update, using a Gaussian proposal distribution with mean equal to the

current point and standard deviation s^η. Since Metropolis updates are reversible, $\underline{T}_\eta$ was the same.

Two sets of forward and reverse LIS runs were done with $n = 4$, all $K_j = 50$, and $M = 20$, one set using the geometric bridge, the other using the optimal bridge with the true value of r. The forward estimates were computed from equation (10); the reverse estimates from equation (22), which is equivalent to using the forward procedure with the reverse sequence of distributions. Bridged LIS estimates were also found using equation (27), with the value of r found by iteration. To make the comparison with forward and reverse estimates fair, the bridged LIS estimates used $M = 10$ — ie, only half of the forward and half of the reverse runs were used, for a total of 20 runs.

A corresponding set of forward, reverse, and bridged AIS runs were also done, with $n = 250$ and $M = 20$ ($M = 10$ for the bridged estimates). If sampling a point from π_0 or π_1 takes about the same computation time as a Metropolis update, these AIS runs will take about the same time as the LIS runs. (This assumes that sampling and Markov transitions dominate the time, which is typically true for real problems but perhaps not for this simple test problem.)

Sets of longer LIS and AIS runs were also done, which were the same as the sets above except that for LIS, $K_j = 200$ for all j, and for AIS, $n = 1000$, which again equalizes the computation time.

Experience, together with the asymptotic results of Section 3.1, shows that estimates produced using a small value of M are better than, or at least as good as, those produced with larger M. I chose $M = 20$ ($M = 10$ for bridged estimates) since this is about the smallest value that allows reliable estimation of standard errors, which would usually be needed in practice.

The standard errors for AIS and LIS estimates of $\hat{r}$ were estimated by the sample standard deviation of the $\hat{r}^{(i)}$ divided by $\sqrt{M}$. When comparing the methods, I looked primarily at the mean squared error when estimating $\log(r)$ (rather than when estimating r). The estimate I used was $\log(\hat{r})$, and the standard error for this estimate was estimated by the standard error for $\hat{r}$ divided by $\hat{r}$. For the reverse runs, $\log(r)$ was estimated by $-\log(\underline{\hat{r}})$. For bridged AIS and LIS, the standard errors for the log of the numerator and the log of the denominator of equation (27) were found, and the overall standard error was computed as the square root of the sum of the squares of these two standard errors. This method of converting estimates and standard errors for r to those for $\log(r)$ is valid asymptotically. It might be improved upon for finite samples, but such improvements would probably not affect the relative merits of the methods compared here.

Figures 3 through 8 plot the mean squared errors of estimates for $\log(r)$ for the six sets of runs. Results are shown for AIS, for LIS using the geometric bridge, and for LIS using the optimal bridge, with the true value of r. Results for both the forward and reverse versions of each method are shown, together with the bridged version, using the optimal bridge, with r obtained by iteration. Results for the short runs ($n = 4$, $K_j = 50$ for LIS, $n = 250$ for AIS) are on the left, and for the long runs ($n = 4$, $K_j = 200$ for LIS, $n = 2000$ for AIS) on the right. The mean squared error for each method was estimated by simulating each method 2000 times, and comparing the estimates with the true value of $\log(r)$. The bars in the plots are dark up to the estimated mean squared error minus twice its standard

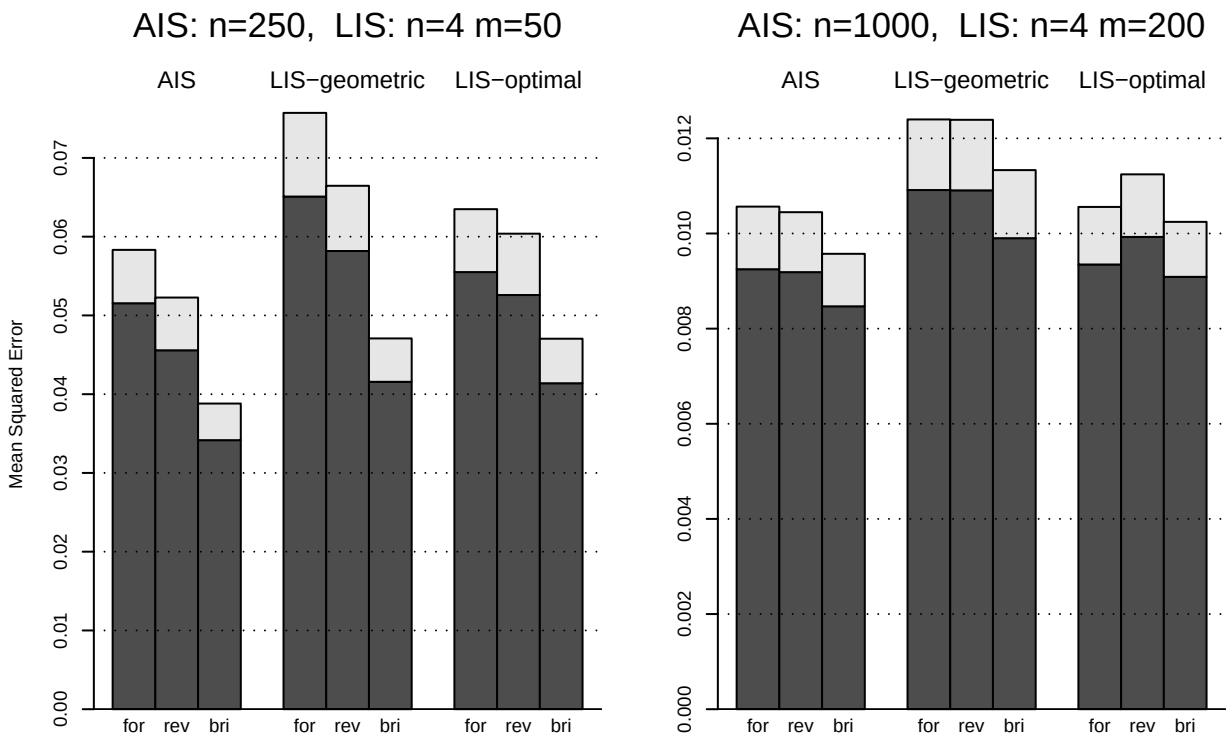

Figure 3: Results of short and long runs on the distribution sequence with $s=1$, $t=4$, and $q=2$.

error, and are then light up to the estimated mean squared error plus twice its standard error. For bars that extend above the plot the estimated mean squared error is shown at the top of the bar.

The results for translated sequences of distributions ($t=4$ and $s=1$) are shown in Figures 3 and 4. When the distributions are Gaussian ($q=2$), no advantage is seen for LIS — if anything, LIS performs slightly worse than AIS, particularly when the geometric bridge is used. The forward and reverse forms of AIS and LIS should have identical performance for these distribution sequences, due to symmetry; any differences seen result from random variation. The bridged forms of both AIS and LIS perform better than the unbridged forward and reverse forms. The advantage of bridging is less for the longer runs, however, as expected from the analysis at the end of Section 3.1.

When $q=10$, the distributions have much lighter tails than the Gaussian, more closely resembling the uniform distributions analysed in Section 3.2. For these sequences of distributions, LIS performs substantially better than AIS. The unbridged version of AIS does particularly badly. The mean squared error for the bridged version of AIS is about 2.5 times greater than for the bridged version of LIS. It makes little difference whether the geometric or optimal bridge is used for LIS.

Figures 5 and 6 show the results for sequences of distributions with the same mean ($t=0$) but decreasing width ($s=0.05$). For these sequences, a modest advantage of LIS over AIS is apparent for the sequence of Gaussian distributions ($q=2$), with the variance for AIS estimates being about a factor of 1.3 greater than for LIS estimates with the geometric bridge, and about a factor of 1.7 greater than for LIS estimates with the optimal bridge. The reversed AIS and LIS estimates are somewhat worse than the forward estimates for this sequence of distributions. No advantage is seen for bridged AIS or LIS estimates.

The results for the sequence of distributions with $q=10$ is similar, except that the advantage of LIS over AIS is much greater — about a factor of 6.

Results for the last type of sequence, with $s=0.3$ and $t=2$, are shown in Figures 7 and 8. This problem is a hybrid of the previous two, with both translation and change in width, producing results intermediate between those for the previous two problems. No difference in performance between AIS and LIS is apparent for the Gaussian distributions ($q=2$), but the bridged forms of both perform slightly better. For the sequence of distributions with $q=10$, a clear advantage of LIS over AIS can be seen, but this advantage is not as great as for the sequence with $t=0$ and $s=0.05$. The bridged forms of both AIS and LIS are again better, more so for the short runs than for the long runs.

In addition to looking at the mean squared error of estimates found with these methods, I also looked at the fraction of times that the estimate for $\log(r)$ differed from the true value by more than twice the standard error estimated using the M runs. This should be approximately 5% if the distribution of estimates is Gaussian, and the standard errors are accurate. For the longer runs, this fraction was indeed near or only slightly above 5% for all methods, except for the unbridged AIS runs when these performed very poorly. For the shorter runs, however, the unbridged AIS and LIS methods produced estimates more than two standard errors from the mean around 10% of the time (sometimes

much more often, when unbridged AIS performed poorly). Both the bridged AIS and the bridged LIS methods gave more reliable standard errors. However, it is possible that better standard errors for the unbridged methods might be obtained with a more sophisticated approach than I used.

I performed additional runs to verify and extend some of the analytic results from Section 3. Figures 9 and 10 show results obtained using LIS with increasing numbers of intermediate distributions, starting with the value of $n = 4$ used for the tests above, and continuing to $n = 9$, $n = 19$, and $n = 39$, while keeping the computation time constant by decreasing m in proportion to $n+1$. The two distribution sequences with $s = 1$ and $t = 4$ and with $s = 0.05$ and $t = 0$ were used, in both cases with $q = 10$. The sequence with $t = 0$ and $s = 0.05$ has the form of equation (33), so in accordance with the analysis of Section 3.1, we expect that asymptotically, as n increases, LIS and AIS should have the same performance. This is indeed what we see in Figure 9. We also see the same behaviour for the sequence with $t = 4$ and $s = 1$ in Figure 10.

As q increases, the distributions become close to uniform, and the results of Section 3.2 should apply. To test this, I tried values of $q = 2$, $q = 10$, $q = 20$, and $q = 30$ for the distribution sequence with $s = 1$ and $t = 4$ and the sequence with $s = 0.05$ and $t = 0$. Results are shown in Figures 11 and 12. (The results for $q = 2$ and $q = 10$ are the same as on the left in Figures 3 to 6, though the scale differs.)

For the sequences with $s = 1$ and $t = 4$, the limiting uniform distributions have the form of the second example in Section 3.2. As noted there, AIS estimates do not converge to the correct value of r for this distribution sequence; bridged AIS estimates do converge, but may be rather inefficient. We see analogous behaviour in Figure 11 when q is large. The mean squared error of the AIS estimates increases approximately linearly with q over the range $q = 10$ to $q = 30$. The bridged AIS estimates also get worse as q increases, but more slowly. In contrast, the mean squared error of the LIS estimates changes hardly at all as q increases.

The story is similar for sequences with $s = 0.05$ and $t = 1$, for which the limiting uniform distributions correspond to those in the first example of Section 3.2. The LIS estimates perform about equally well for all values of q, but the AIS estimates are dramatically worse for large values of q. For this sequence, reverse AIS estimates are much worse than forward AIS estimates, and bridging does not help.

According to the analysis of Section 3.1, the choice of choice of $n = 4$ for LIS used above is not optimal for either of these distribution sequences when q is large. For the sequence with $s = 1$ and $t = 4$, using $n = 6$ should be better by a factor of 1.176. However, in LIS runs with $q = 30$, the mean squared error using $n == 4$ and $m = 200$ is indistinguishable from that using $n = 6$ and $m = 143$, given the standard errors (a factor of 1.09 or more should have been detectable). Of course, $q = 30$ does not give exactly uniform distributions, and these values of m may not be large enough for the asymptotic results to apply, especially since the Markov transitions do not sample independently. For the sequence with $s = 0.05$ and $t = 0$, the results in Section 3.1 indicate that using $n = 3$ should be better by a factor of 1.084. In this case, LIS runs with $q = 30$ using $n = 3$ and $m = 250$ are better than runs using $n = 4$ and $m = 200$ by a factor of 1.16, significantly greater than one given the standard errors, but not significantly different from the expected ratio of 1.084.

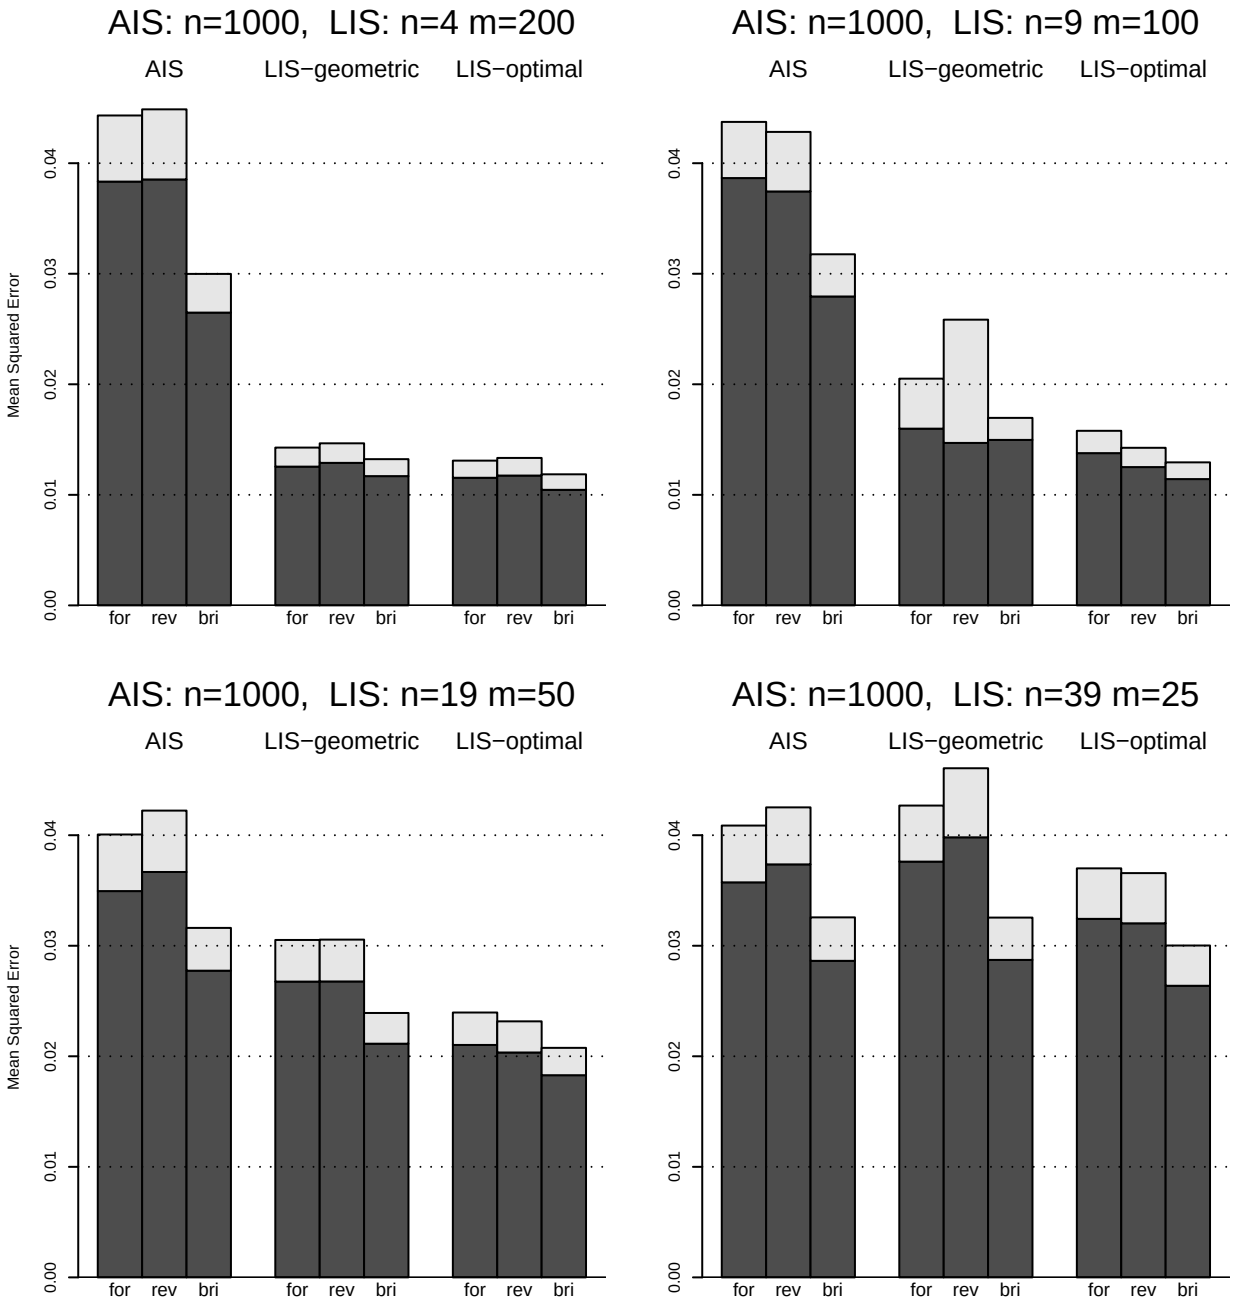

Figure 9: Results using increasing values of n for LIS, while keeping computation time constant, for the distribution sequence with $s=1$, $t=4$, and $q=10$. The same AIS procedure was used for all plots, but results vary randomly.

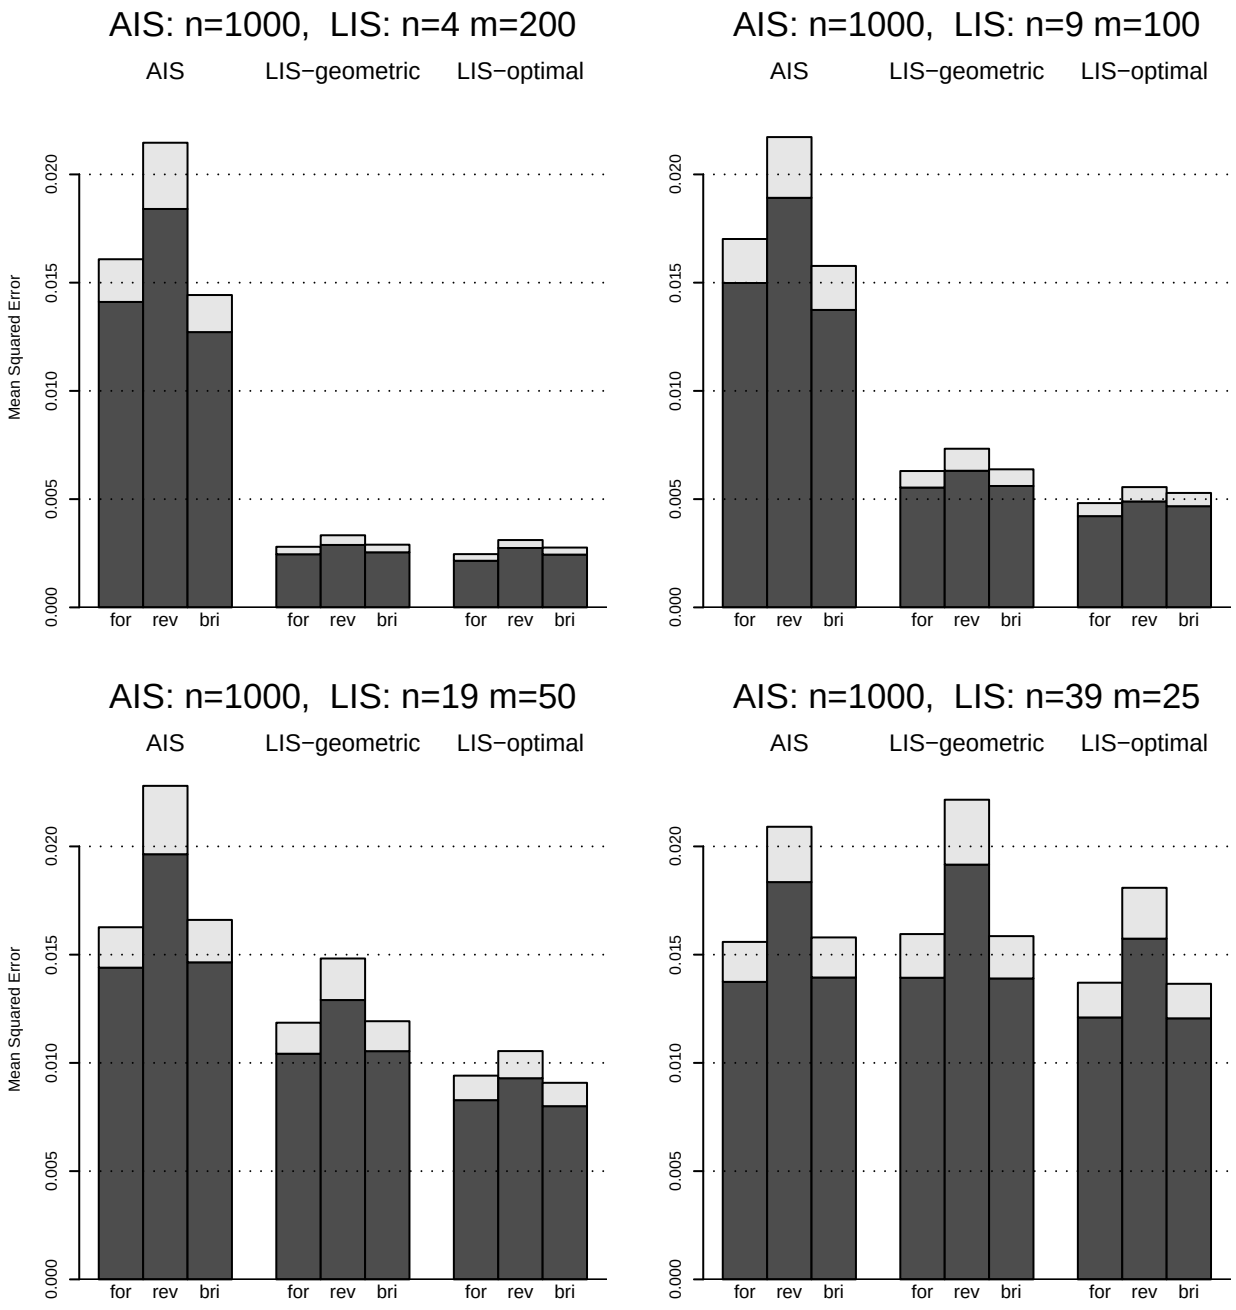

Figure 10: Results using increasing values of n for LIS, while keeping computation time constant, for the distribution sequence with $s = 0.05$, $t = 0$, and $q = 10$. The same AIS procedure was used for all plots, but results vary randomly.

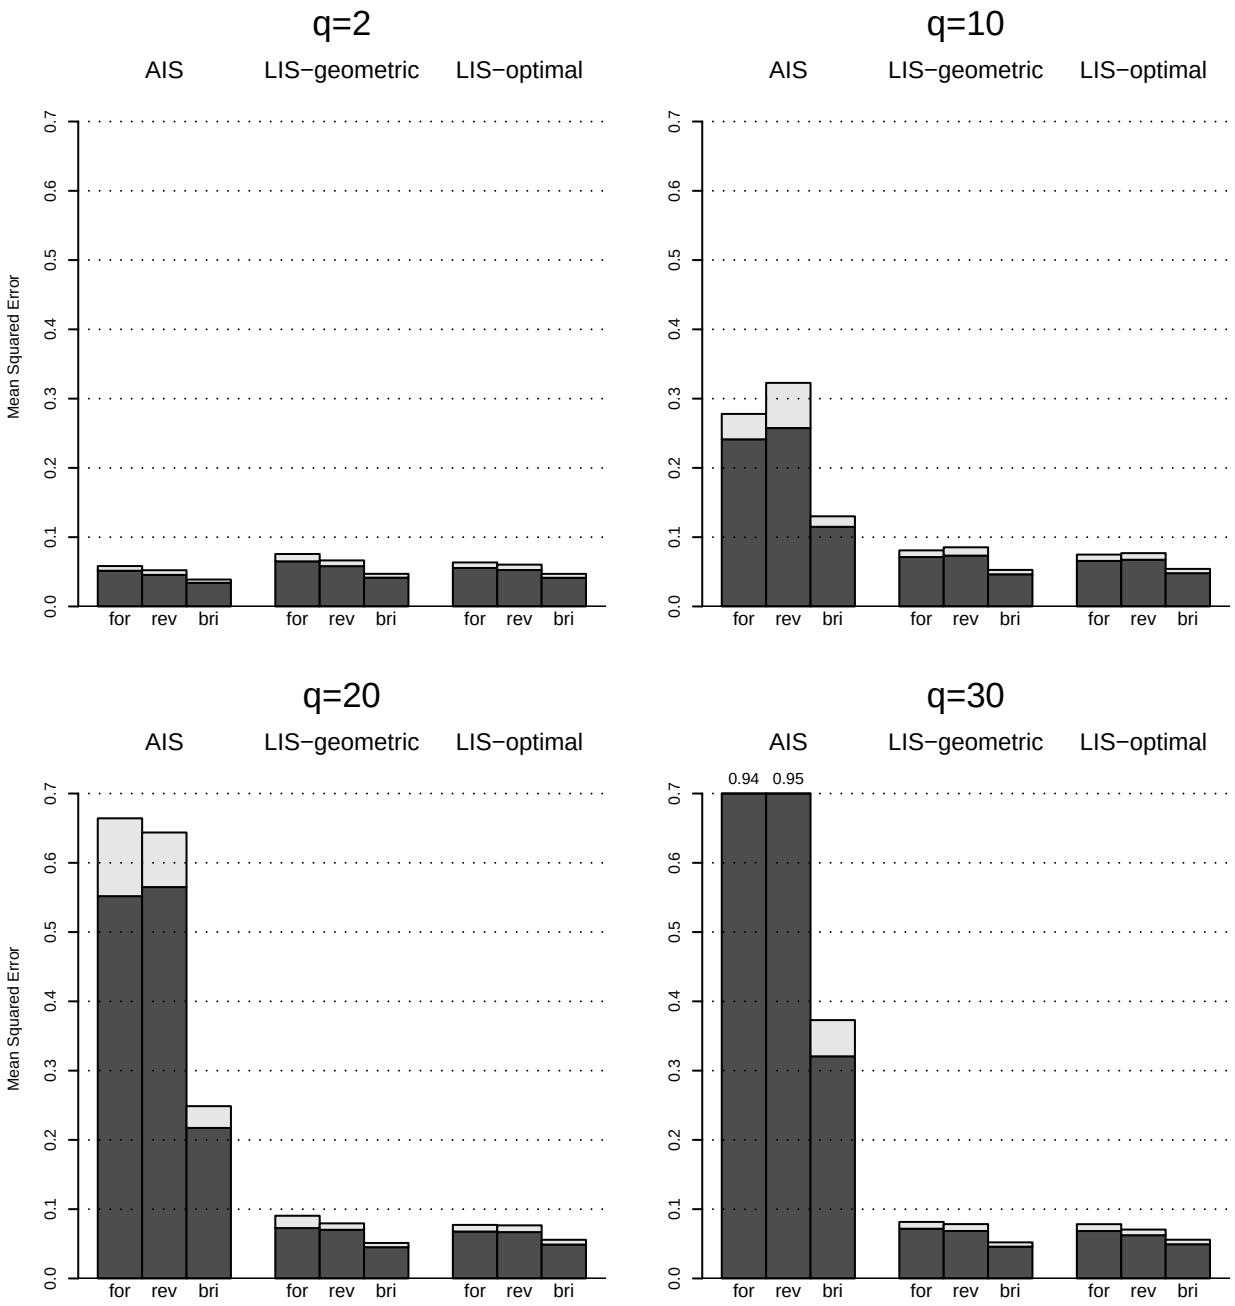

Figure 11: Results with increasing values of q, for sequences of distributions with $s=1$ and $t=4$. The AIS runs used $n=250$; the LIS runs used $n=4$ and $m=50$, requiring the same amount of computation.

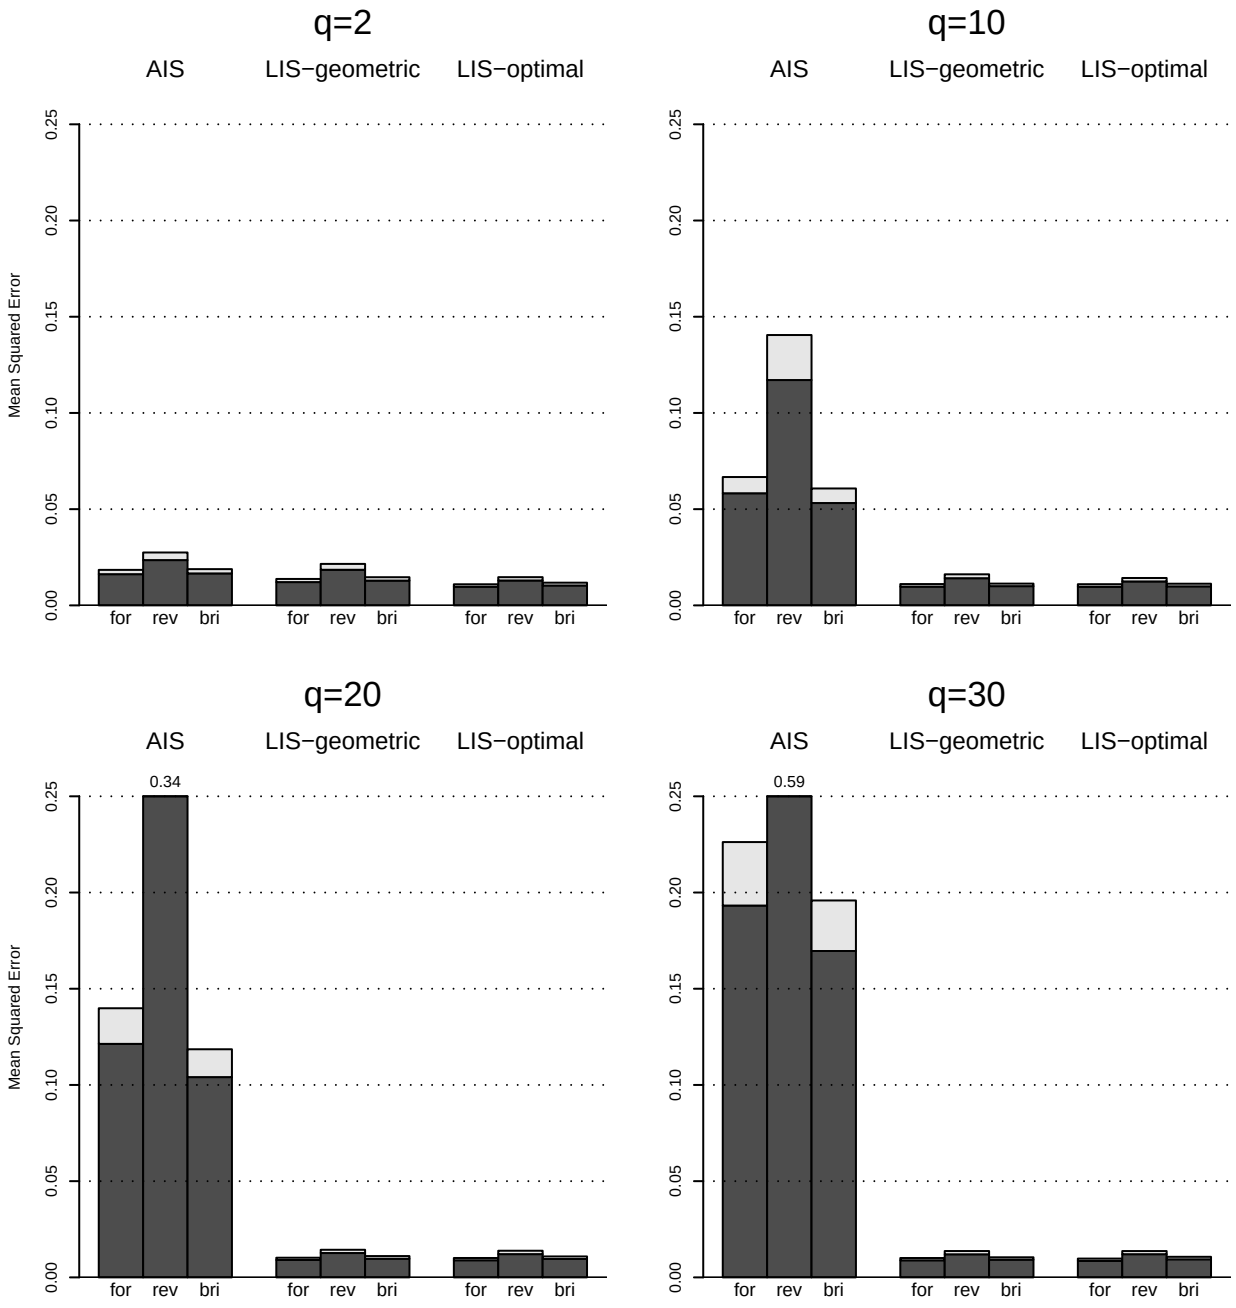

Figure 12: Results with increasing values of q, for sequences of distributions with $s = 0.05$ and $t = 1$. The AIS runs used $n = 250$; the LIS runs used $n = 4$ and $m = 50$, requiring the same amount of computation.

5 Other applications of linked sampling

So far in this paper, I have focused on how Linked Importance Sampling can be used to estimate ratios of normalizing constants. LIS can also be used to estimate expectations with respect to π_1, however, and in some applications, this may be its most important use. Linked sampling methods related to LIS can also be applied in other ways. I briefly described these other applications here, outlining the use of linked sampling for 'dragging' fast variables in some detail.

5.1 Estimating expectations

The expectation of some function, $a(x)$, with respect to π_1 can be estimated using simple importance sampling, with points drawn from π_0, as follows:

$$E_{\pi_1}[a(X)] \;=\; E_{\pi_0}\left[a(X)\frac{p_1(X)}{p_0(X)}\right] \Big/ \frac{Z_1}{Z_0} \;\approx\; \frac{1}{N}\sum_{i=1}^{N} a(x^{(i)})\,\frac{p_1(x^{(i)})}{p_0(x^{(i)})} \Big/ \frac{1}{N}\sum_{i=1}^{N} \frac{p_1(x^{(i)})}{p_0(x^{(i)})} \tag{49}$$

where $x^{(i)}, \ldots, x^{(N)}$ are drawn from π_0. Like equation (2), this estimate is valid only if no region having zero probability under π_0 has non-zero probability under π_1. The two factors of $1/N$ of course cancel, but are included to emphasize the connection with the estimate for $r = Z_1/Z_0$, which is simply the denominator of the estimate above.

Since LIS can be viewed as simple importance sampling on an extended state space, with distributions Π_0 and Π_1 defined by the forward and reverse procedures of Section 2, we can use equation (49) to estimate any quantity that can be expressed as an expectation with respect ot Π_1. Step (1) of the reverse procedure defining Π_1 sets x_{n,μ_n} to a value randomly chosen from $\pi_{\eta_n} = \pi_1$. Step (2) then sets the other $x_{n,k}$ to values obtained from x_{n,μ_n} by applying Markov chain transitions that leave π_1 invariant. It follows that under Π_1, all the points $x_{n,k}$ have marginal distribution π_1 (though they may not be independent). Accordingly,

$$E_{\pi_1}[a(X)] \;=\; E_{\Pi_1}\left[\frac{1}{K_n+1}\sum_{k=0}^{K_n} a(X_{n,k})\right] \tag{50}$$

Estimating the right side as in equation (49), and using the fact that the ratio of probabilities under Π_1 over those under Π_0 is given by $\hat{r}^{(i)}_{\mathrm{LIS}}$ in equation (10), we get the estimate

$$E_{\pi_1}[a(X)] \;\approx\; \sum_{i=1}^{M} \frac{\hat{r}^{(i)}_{\mathrm{LIS}}}{K_n+1} \sum_{k=0}^{K_n} a(x^{(i)}_{n,k}) \Big/ \sum_{i=1}^{M} \hat{r}^{(i)}_{\mathrm{LIS}} \tag{51}$$

If the M runs of LIS are started by sampling independently from π_0 (as will often be possible), the standard error of this estimate can be assessed in the usual fashion for importance sampling, as I have discussed for the analogous AIS estimates in (Neal 2001). This error assessment can be difficult, since when some $\hat{r}^{(i)}_{\mathrm{LIS}}$ are much larger than others, the variance of $\hat{r}^{(i)}_{\mathrm{LIS}}$ is hard to estimate. Note, however, that the degree to which the Markov chain transitions used have converged need not be assessed, a

possible advantage compared with simple MCMC estimates. The estimate of equation (51) will be asymptotically correct (as $M \to \infty$) regardless of how far these Markov chain transitions are from convergence.

The primary reason one might wish to use LIS to estimate expectations is that going through the sequence of distributions parameterized by $\eta_0, \ldots, \eta_n$ may produce an 'annealing' effect, which prevents the Markov chain sampler from being trapped in a local mode of the distribution. Compared with the analogous AIS procedure, LIS may perform better for some forms of distributions, for the same reasons as were discussed in Sections 3 and 4. One should also note that LIS estimates for expectations with respect to π_{η_j} for all j can easily be obtained from a single set of runs, by simply considering the results of each LIS run up to the point where the sample for π_{η_j} is obtained.

5.2 A linked form of tempered transitions

My 'tempered transition' method (Neal 1996) is another approach to sampling from distributions with isolated modes, between which movement is difficult for Markov chain transitions such as simple Metropolis updates. In this approach, such simple Markov chain transitions are supplemented by occasional complex 'tempered transitions', composed of many simple Markov chain transitions. A tempered transition consists of several stages, which proceed through a sequence of distributions, from the distribution being sampled, to a 'higher temperature' distribution in which movement between modes is easier, and then back down to the distribution being sampled. At each stage of a tempered transition, we generate a single new state by applying a Markov chain transition to the current state, after which we switch to the next distribution in the sequence. The second half of a tempered transition is similar to an Annealed Importance Sampling run, while the first half is similar to an AIS run with the reversed sequence of distributions.

A similar 'linked' procedure can be defined, in which at each stage we generate a chain of states by applying a Markov chain transition. We then select a 'link state' from this sequence (using a suitable bridge distribution) which serves as the starting point for the chain of states generated in the next stage. In the final stage, a chain of states is produced using a Markov chain transition that leaves the distribution being sampled invariant, and a candidate state is selected uniformly at random from this chain. The appropriate probability for accepting this candidate state is computed using ratios similar to those going into the LIS estimate of equation (10).

As discussed in Section 4, for AIS to work well, all distributions in the sequence must assign reasonably high probability to regions of the space that have non-negligible probability under the next distribution in the sequence. One would expect tempered transitions to work well only when this holds for both the sequence and its reversal. In contrast, one would expect the 'linked' version of tempered transitions to work well as long as the sequence satisfies the weaker condition that there be some 'overlap' between adjacent distributions (assuming a suitable bridge distribution is used).

5.3 Dragging fast variables using linked chains

A slight modification of the tempered transition method can be applied to problems in which the state is composed of both 'fast' and 'slow' variables. We will write the distribution of interest for such a problem as

$$\pi(x,y) \;\; = \;\; (1/Z)\,\exp(-U(x,y)) \tag{52}$$

where x denotes the 'fast' variables and y the 'slow' variables. We assume that the computation is dominated by the time required to evaluate $U(x,y)$, but that once $U(x,y)$ has been evaluated, with relevant intermediate quantities saved, evaluating $U(x',y)$ for any new x' is much faster than evaluating $U(x',y')$ for some y' not previously encountered. One example of such a problem is inference for Gaussian process classification models (Neal 1999), in which y consists of the hyperparameters defining the covariance function used, and x consists of the latent variables associated with the n observations. After a change to y, we must recompute the Cholesky decomposition of an $n \times n$ covariance matrix, which takes time proportional to n^3, whereas after a change to x only, $U(x,y)$ can be re-computed in time proportional to n^2, assuming the Cholesky decomposition for this value of y has been saved.

In my method for 'dragging' fast variables (Neal 2004), the ability to quickly re-evaluate $U(x,y)$ when only x changes is exploited to allow larger changes to be made to y than would be possible if x were kept fixed, or were given a new value from some simple proposal distribution. From the state (x_0,y_0), a dragging update proposes a new value y_1, drawn from some symmetrical proposal distribution, in conjunction with a new value x_1 that is found by applying a succession of Markov chain updates that leave invariant distributions in the series, $\pi_{\eta_j}(x)$, for $j = 1,\ldots,n-1$, with $0 < \eta_j < \eta_{j+1} < 1$. The proposed state, (x_1,y_1), is then accepted or rejected in a fashion analogous to tempered transitions.

The distributions in the sequence used are defined by the following unnormalized probability or density function, which depends on the current and proposed values for y:

$$p_\eta(x) \;\; = \;\; \exp\left(-\left((1-\eta)\,U(x,y_0) \;+\; \eta\,U(x,y_1)\right)\right) \tag{53}$$

The corresponding normalized probability or density function will be written as π_η. Note that $\pi_0(x) = \pi(x|y_0)$ and $\pi_1(x) = \pi(x|y_1)$. Crucially, after $U(x,y_0)$ and $U(x,y_1)$ have been evaluated once (for any x), we can evaluate $p_\eta(x)$ for any η and any x without any further 'slow' computations. Indeed, since $U(x_0,y_0)$ will usually have already been evaluated as part of the previous Markov chain transition, only one slow computation will be required to evaluate $p_\eta(x)$ for any number of values of η and x.

A 'linked' dragging update can be defined as follows. Given the sequence of distributions defined by $\eta_0,\ldots,\eta_n$, with $\eta_0 = 0$ and $\eta_n = 1$, the numbers of transitions (T or $\underline{T}$) to perform for each distribution over x, denoted by $K_0,\ldots,K_n$, and a set of bridge distributions, denoted by p_{j*j+1}, for $j = 0,\ldots,n-1$, an update from the current state (x_0,y_0) is done as follows:

The Linked Dragging Procedure

1) Propose a new value, y_1, from some proposal distribution $S(y_1|y_0)$, which satisfies the symmetry condition that $S(y_1|y_0) = S(y_0|y_1)$.

2) Pick an integer ν_0 uniformly at random from $\{0, \ldots, K_0\}$, and then set x_{0,ν_0} to the current values of the fast variables, x_0.

3) For $j = 0, \ldots, n$, create a chain of values for x associated with π_{η_j} as follows:

   a) If $j > 0$: Pick an integer ν_j uniformly at random from $\{0, \ldots, K_j\}$, and then set x_{j,ν_j} to x_{j-1*j}.

   b) For $k = \nu_j + 1, \ldots, K_j$, draw $x_{j,k}$ according to the forward Markov chain transition probabilities $T_{\eta_j}(x_{j,k-1}, x_{j,k})$. (If $\nu_j = K_j$, do nothing in this step.)

   c) For $k = \nu_j - 1, \ldots, 0$, draw $x_{j,k}$ according to the reverse Markov chain transition probabilities $\underline{T}_{\eta_j}(x_{j,k+1}, x_{j,k})$. (If $\nu_j = 0$, do nothing in this step.)

   d) If $j < n$: Pick a value for μ_j from $\{0, \ldots, K_j\}$ according to the following probabilities

$$\Pi_0(\mu_j \,|\, x_j) \;=\; \frac{p_{j*j+1}(x_{j,\mu_j})}{p_{\eta_j}(x_{j,\mu_j})} \;\Big/\; \sum_{k=0}^{K_j} \frac{p_{j*j+1}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \tag{54}$$

   and then set x_{j*j+1} to x_{j,μ_j}.

3) Set μ_n to a value chosen uniformly at random from $\{0, \ldots, K_n\}$, and let the proposed new values for the fast variables, x_1, be equal to x_{n,μ_n}.

4) Accept (x_1, y_1) as the new state with probability

$$\min \left\{ 1, \; \prod_{j=0}^{n-1} \left[\frac{1}{K_j + 1} \sum_{k=0}^{K_j} \frac{p_{j*j+1}(x_{j,k})}{p_{\eta_j}(x_{j,k})} \;\Big/\; \frac{1}{K_{j+1} + 1} \sum_{k=0}^{K_{j+1}} \frac{p_{j*j+1}(x_{j+1,k})}{p_{\eta_{j+1}}(x_{j+1,k})} \right] \right\} \tag{55}$$

   If (x_1, y_1) is not accepted, the new state is the same as the old state, (x_0, y_0).

One can show that this update leaves $\pi(x, y)$ invariant by showing that it satisfies detailed balance, which in turns follows from the stronger property that the probability of starting at (x_0, y_0), assuming this start state comes from $\pi(x, y)$, then generating the various quantities produced by the above procedure, and finally accepting (x_1, y_1) as the new state, is the same as the probability of starting this procedure at (x_1, y_1), generating the same quantities in reverse, and finally accepting (x_0, y_0). The proof of this is analogous to the derivation of LIS in Section 2.

To use the linked dragging procedure, we need to select suitable bridge distributions. Since the characteristics of $\pi_\eta(x)$ will depend on y_0 and y_1, and of course η, we may not know enough to select good estimates for the values of r needed to use the optimal bridge of equation (6), though we might

try just setting r to one. This is not a problem for the geometric bridge of equation (5), for which the acceptance probability above can be written as

$$\min \left\{ 1, \prod_{j=0}^{n-1} \left[\frac{1}{K_j+1} \sum_{k=0}^{K_j} \sqrt{\frac{p_{\eta_{j+1}}(x_{j,k})}{p_{\eta_j}(x_{j,k})}} \Big/ \frac{1}{K_{j+1}+1} \sum_{k=0}^{K_{j+1}} \sqrt{\frac{p_{\eta_j}(x_{j+1,k})}{p_{\eta_{j+1}}(x_{j+1,k})}} \right] \right\} \tag{56}$$

From equation (53), we see that

$$\frac{p_{\eta_{j+1}}(x_{j,k})}{p_{\eta_j}(x_{j,k})} = \exp\left(-(\eta_{j+1}-\eta_j)\left(U(x_{j,k},y_1)-U(x_{j,k},y_0)\right)\right) \tag{57}$$

$$\frac{p_{\eta_j}(x_{j+1,k})}{p_{\eta_{j+1}}(x_{j+1,k})} = \exp\left(-(\eta_{j+1}-\eta_j)\left(U(x_{j+1,k},y_0)-U(x_{j+1,k},y_1)\right)\right) \tag{58}$$

For the simplest case with no intermediate distributions (ie, with $n=1$), the acceptance probability simplifies to

$$\min \left\{ 1, \frac{\frac{1}{K_0+1} \sum_{k=0}^{K_0} \exp\left(-\left(U(x_{j,k},y_1)-U(x_{j,k},y_0)\right)/2\right)}{\frac{1}{K_1+1} \sum_{k=0}^{K_1} \exp\left(-\left(U(x_{j,k},y_0)-U(x_{j,k},y_1)\right)/2\right)} \right\} \tag{59}$$

6 Conclusions and Future work

In this paper, I have demonstrated that in some situations Linked Importance Sampling is substantially more efficient than Annealed Importance Sampling, provided a suitable number of intermediate distributions are used. However, in other situations, where the tails of the distributions involved are sufficiently heavy, the two methods are about equally efficient. More research is therefore needed to determine for which problems of practical interest LIS, and related linked sampling methods, will be useful.

In tests on multivariate Gaussian distributions, I have not seen an advantage for LIS over AIS. Both perform about equally well on a sequence of 100-dimensional spherical Gaussian distributions with variances changing by a factor of two, so that $\log(r) = -100$. This is in accord with the results in Section 4, where LIS had little or no advantage over AIS when the distributions were Gaussian. LIS is more likely to be useful for problems involving continuous distributions with lighter tails.

One problem that may benefit from LIS is that of computing the probability of a very rare event, which can be cast as computing the normalizing constant for a distribution with the constraint that the state be in the set corresponding to this event. Intermediate distributions might use looser forms of this constraint. If, in all these distributions, states violating the constraints have zero probability, AIS will tend to have the same bad behaviour seen with uniform distributions in Section 3.2, while LIS may work much better.

Another context where LIS may outperform AIS is when only a fixed number of intermediate distributions are available — ie, only a finite number of values are allowed for η. This is the situation for the 'sequential importance sampler' of MacEachern, Clyde, and Liu (1999), which can be seen as an instance of AIS (Neal 2001). Here, the intermediate distributions use only a fraction of the n items in the data set; such a fraction can only have the form j/n with j an integer. The distance between successive distributions for this problem may sometimes be too great for AIS to work well, but their overlap might nevertheless be sufficient for LIS.

It may be possible to improve LIS by reducing the variance in how well it samples at each stage. Instead of performing a predetermined number, K_j, of Markov transitions at stage j, we might instead perform as many transitions as are necessary to obtain a good sample. Define a 'tour' to be a sequence of transitions that moves from a high value of some key quantity (eg, $U(x)$ for the canonical distributions of equation (1)) to a low value of this quantity, or vice versa. Good sampling might be ensured by performing some predetermined number of tours, with the number of these tours that occur before and after the link state being chosen at random. Suitable 'high' and 'low' values would probably need to be found using preliminary runs.

More speculatively, it seems as if there should be some method that has the advantages of LIS over AIS, but that like AIS uses many intermediate distributions, performing only a single Markov transition for each. Intuitively, it seems that such a 'smooth' method that does not abruptly change η should be more efficient. One can use LIS with all K_j set to one, but this will produce good results only if n is large, which we saw in the analysis of Section 3.1 does not lead to an advantage over AIS. Perhaps some way could be found of using states associated with all values of η when estimating each of the ratios $Z_{\eta_{j+1}}/Z_{\eta_j}$, while still producing an estimate that is exactly unbiased even when the Markov transitions do not reach equilibrium.
